NUMBER 1

THE TREATMENT OF PNEUMONIA

By RUFUS COLI, M.D. *New York, N. Y.*

THIRTY years ago Dr. Osler wrote, "Pneumonia is a self-limited disease, which can neither be aborted nor cut short by any means at our command." When I went to the Rockefeller Institute shortly afterwards, I said to myself, "Here, at least, is a wide open field. This is the most serious acute infectious disease with which physicians have to deal. Is it possible that nothing can be done to decrease the frightful mortality due to this malady? At any rate, we can attempt to obey St. Paul's injunction, 'Prove all things, hold fast that which is good.'" From that time to this, my associates and I have tested many new things, and while we have tried to hold fast to that which is good, we may have failed to see the nuggets scattered among the rubbish, and time and the work of others may show that certain methods which I may reject today, or condemn with faint praise, if properly applied, are of value.

Before any judgment may be drawn regarding the value of any form of treatment, clear-cut definition must be made of the condition in which the therapy is applied. It is useless to speak of the value of any form of treatment in pneumonia unless all the cases are sufficiently alike that we may consider this disease a clinical entity. The term "pneumonia," however, is now applied to all those conditions in which there occurs an acute exudative inflammation involving the parenchyma of the lungs. But that leaves us about where we were less than a hundred years ago, in our conception of acute abdominal diseases, when typhoid, paratyphoid, appendicitis, peritonitis, dysentery, and diarrhea were all spoken of as "inflammation of the bowels." The development of pathological anatomy was followed by the grouping of all cases of pneumonia into two forms, one, in which complete lobes are involved, lobar pneumonia, and second, those in which the involvement is irregular and patchy, bronchopneumonia. But today even the pathologist, with the tissues before him, frequently hesitates to say whether the condition from which the patient suffered should be called lobar or bronchopneumonia.

* Read at the Detroit meeting of the American College of Physicians, March 5, 1936.
From the Hospital of the Rockefeller Institute for Medical Research, New York.

From the standpoint of therapy this anatomical differentiation of cases has been of little value, and so far as therapy directed toward overcoming the specific etiologic agents is concerned, it is almost worthless. However, the term "lobar pneumonia" is today well established in medical literature. It would be impossible, even if desirable, to supplant it, but it adds very much to its usefulness if it be limited to cases in which pneumococcus is demonstrated to be the etiologic agent. All the other cases of pneumonia, due to streptococci, staphylococci, etc., may be included under the term "atypical pneumonia," also not a good term, but I know of none better. Today, I shall confine my attention to acute lobar pneumonia, that is, acute pneumococcus infection of the lungs.

For specific treatment, an etiologic diagnosis is essential, but before this is made it must first be determined whether or not the patient is really suffering from pneumonia, and this should be decided as early as possible.

At present, most physicians wait for the appearance of physical signs of consolidation before making a diagnosis. Patient after patient has been sent into our hospital with the statement that he has been suffering with severe symptoms for three, four, five, or even more days, but that the signs of pneumonia have just appeared.

The truth of the matter is that evidence of consolidation is not necessary for the diagnosis of pneumonia. To the experienced observer the symptoms of the onset of this disease are, in most cases, definite and unmistakable. In almost all cases the person who has a chill, fever over 102° , cough, pain in the side, rapid respirations, and, above all, who is expectorating sputum which is bloody or even only slightly tinged with blood, has pneumonia. Even in persons who have suffered from cough or mild upper respiratory infections before the onset, as is the history in 60 per cent of the cases, the appearance of the more serious pulmonary infection is, in most instances, clearly indicated by the more or less sudden appearance of the symptoms I have mentioned. We physicians have made the diagnosis of pneumonia too difficult, and it is much less harmful to make an occasional mistake than to live in fancied security for days until the time when specific treatment would be useful is passed. Most cases *threatened* with pneumonia have pneumonia.

The determination of the etiologic agents in all cases of pneumonia involves difficulties, but in my opinion they are not unsurmountable. Fortunately, laboratory methods are now available by means of which this can be accomplished with little delay. By the so-called Neufeld method, all that is necessary is to treat the sputum with rabbit immune sera of the various types. If, for instance, the organisms are of Type I, swelling of the capsules occurs in Type I serum and in sera of no other types. In probably the majority of cases of pneumonia, the matter is really as simple as this, but not in all, and the physician as well as the bacteriologist must take some trouble and pains. The examination of sputum should be considered an

emergency procedure It should not be delayed until the next morning or until other work is out of the way

SERUM THERAPY

Twenty-two years ago at the Hospital of the Rockefeller Institute, we began the treatment of lobar pneumonia with specific immune serum This was undertaken because evidence derived from animal experimentation indicated that the procedure was theoretically sound During the intervening years the efficacy of serum treatment in animals has been abundantly demonstrated Blake and Cecil have shown that monkeys suffering from experimental pneumonia may be cured by the injection of homologous antipneumococcus horse serum, even after the pneumonic process is well established, and Goodner has demonstrated the curative value of immune serum in the much more susceptible rabbits even when the administration of serum is delayed as long as 72 hours following infection

But demonstrations in animals are not sufficient We must know by actual experience whether or not serum treatment in man is effective Our first observations in man gave to me very convincing evidence that if sufficient serum be used, and used promptly, true curative effects were obtained in cases due to Type I pneumococci The evidence was less convincing in the cases due to Type II organisms

During these years we have treated with serum all cases of Type I pneumonia entering the Hospital of the Rockefeller Institute, except, first, an inconsiderable number of children, most of whom recover without serum, second, patients who were moribund on admission and died before treatment could be instituted, and, third, patients who on admission were manifestly in the stage of recovery Until two years ago, whole serum in doses of 100 c c was administered, during the past two years concentrated serum has been used As early as 1915, Avery determined which fraction of the serum contained the immune principles, and demonstrated how concentration of the serum might be accomplished We delayed employing concentrated serum, however, for many years, even after improved methods for concentrating the serum were devised by Felton and others, for the following reasons In the first place, concentration adds materially to the expense of an already very expensive procedure, since in all methods of concentration a large loss of immune substances inevitably occurs Concentrated serum contains nothing which the unconcentrated does not contain In the second place, in our opinion the methods first employed for standardization of the concentrated serum gave entirely misleading information regarding its actual strength With the methods first proposed, it was claimed that a concentration of twenty or more times that of the original serum had been obtained and doses of 5 c c of the concentrated serum were considered adequate Our own observations and experience taught that this was impossible Specific treatment in this serious disease is not of the type of a teaspoonful

three times a day before meals. One cannot discuss whether serum treatment, even in Type I pneumonia, is or is not effective. All depends on how it is used. Even at present, its employment is still a complicated procedure, and for its successful use more knowledge is required than that which is given on the wrappers supplied by the commercial houses.

Several years ago, when the New York State Board of Health was able to supply serum concentrated from good effective serum, and not from weak serum which would otherwise be useless, and when we could be sure that it was standardized by a satisfactory method, we began using this, not in doses of a few c c, but in 15 to 30 c c doses. That is, it has been possible to concentrate the serum three to five times. Using the determination of strength employed by the New York State Board of Health, the doses we have used contain 90,000 units.

The greater ease of administration of the concentrated serum is obvious. In addition, most observers feel that the frequency of immediate reactions is less. This, however, is not certain. Anaphylactic reactions may occur with small amounts of serum as well as with large. Febrile reactions depend very much upon the care with which sera are prepared. Certain lots of unconcentrated sera give febrile reactions in a large proportion of cases, others rarely. In our experience, however, using both concentrated and unconcentrated serum from the same source, the febrile reactions with the concentrated serum have been notably less than with the whole serum. Probably the greatest value in using the concentrated serum consists in a decrease in frequency and severity of the symptoms of serum disease. These symptoms occur, however, with either the concentrated or unconcentrated serum, in at least half of the cases, seven to ten days following the administration of the serum. With present knowledge there is no way in which these unpleasant but harmless symptoms may be completely avoided.

In our clinic 462 cases of Type I pneumonia have now been treated with immune serum. Its value has been judged by the apparent effect on the symptoms, the rapid appearance of immune substances in the blood, the fact that following its administration bacteria disappear from the blood, and on the mortality rate in the patients treated.

Of the 462 treated cases, 48 died, a mortality rate of 10.5 per cent. Since, during the same period, the mortality rate in cases of pneumonia not due to Type I pneumococci has remained at about the same level as that of other hospitals, it seems that the low rate in Type I cases is definitely dependent upon the serum treatment employed.

All cases admitted have been treated as soon as the diagnosis was made. This is of importance because some of those employing serum have recommended that it be used only in cases that can be treated as early as the third or possibly the fourth day. It is true that the effectiveness of the serum is apparently greater the earlier in the disease it is used, but our experience indicates that no patient, however late he is seen, should be deprived of the benefits of this measure. In this series the mortality rate in cases

treated during the first three days was 48 per cent, in those treated on the fourth day or earlier, 82 per cent, on the fifth day or earlier, 86 per cent, and in those treated after the fifth day, 19.5 per cent

In general, our earliest conclusions regarding the value of Type II serum have been confirmed—namely, that it is not sufficiently effective to justify its general use. Sera for treatment in cases due to pneumococci of some of the higher types have now been prepared, and the results with some of them seem to be good, but the experience as yet is not sufficiently large to permit conclusions to be drawn. It is not impossible that with improvements in methods even Type II serum may be made useful. Type III pneumococci differ from the others in their immunological properties, and it is probable that if specific treatment in cases due to these organisms can be developed it will have to be based on different principles. The complaint is sometimes made that, after all, serum treatment is possible in only a part of the cases of pneumonia, and attempts are made to treat all cases either with Type I sera or with so-called polyvalent sera. Type I pneumonia, however, in this country probably causes 25,000 deaths every year, more than twice as many as were ever due to typhoid, even when it was most prevalent. Type I pneumonia should be looked upon as a specific infectious disease, as specific as is typhoid fever, and be treated as such.

From our experience, therefore, Type I serum should be given as early as possible and in large amounts, and the doses should be repeated every four or five hours until definite effects are seen in the fall of temperature, decrease in pulse and respiratory rates, and improvement in the other signs of intoxication. It is better to give too much than too little. Skin tests with soluble specific substance, as proposed by Francis, are useful in determining when sufficient serum has been given, but the observer must have had considerable experience in order to rely on this method alone.

Much stress has been laid upon the possible dangers of violent reactions. There are some risks, but it is now possible to guard against them. That disastrous results did not occur when we first began using very large amounts of serum intravenously, when we did not know the dangers or how to guard against them, shows that the dangers are not too great. By making preliminary tests for serum sensitiveness, by proceeding very slowly in the first injection, and by prompt use of adrenalin in case any symptoms occur, the possibilities of serious serum complications are almost entirely avoided.

CHEMOTHERAPY

The only other form of therapy at present employed in overcoming the infectious agent consists in the use of chemotherapeutic agents, such as optochin and other quinine derivatives. While studies made by Morgenroth and others have demonstrated that in mice infected with pneumococci definite curative effects may be obtained, experimental and clinical studies made in our clinic and elsewhere have shown that in man, in order to obtain

sufficient concentration of the drugs to be effective, such large doses must be employed that toxic effects, notably amblyopia, occur, and that the use of these drugs in human therapy is therefore unjustifiable

It hardly seems necessary to discuss vaccine treatment, since at present it has no experimental or theoretical justification

GENERAL MEASURES

Apart from specific therapy, however, the physician is not entirely without weapons in the struggle with pneumonia, though it must be admitted that they are not very powerful ones

Possibly the most important measure is rest. In the last analysis it is always the patient himself that must overcome the infection, even with the aid of serum, and everything that conserves the patient's strength is of importance. The first advice to be given to patients with pneumonia, even though they do not appear very ill at the onset, is to keep as quiet as possible. The second important point is to reassure them. Fear is as serious an element in the battle with pneumonia as we are told that it is in a financial depression.

MORPHINE

Something may be accomplished with drugs in allaying restlessness, but the ideal drug for this purpose is still to be sought. Formerly I was of the opinion that morphine was of much value in the treatment of pneumonia, and my clinical experience still leads me to believe that, especially in patients with severe pleural pain, in the early stages of the disease, there is no other drug which will so satisfactorily allay the general restlessness and permit the conservation of strength and energy. In view of the more accurate studies of Davis made in our clinic, however, we have become much more conservative in its use. It was found that in most cases following its administration there occurred not only a slowing in respiratory rate, but also a diminution in pulmonary ventilation and a decrease in oxygen saturation of the arterial blood. These changes were not striking, however, and it was found that when the depth of respiratory movements was diminished on account of the pain, the relief following the administration of morphine might result in actual increase in the pulmonary ventilation. In cases of extensive pulmonary involvement with diffuse moist râles, however, the administration of morphine at times resulted in a marked degree of anoxemia.

OXYGEN THERAPY

Probably the most striking functional change seen in pneumonia is rapid, shallow breathing, with deficient saturation of the arterial blood, as indicated by cyanosis. So far no satisfactory specific method for increasing the pulmonary ventilation has been found. The usefulness of breathing air containing an increased percentage of carbon dioxide has been much recom-

mended, but in our experience this procedure has not given significant therapeutic results. While the anoxemia bears some relation to the rapid and shallow breathing, it is probably related in greater measure to the impairment of the respiratory surface of the lungs, especially where there is much fluid exudate.

Twenty years ago, although the inhalation of oxygen in various pathological conditions had been long employed, the value of this procedure was much in doubt, and certain physiologists even claimed that on theoretical grounds its administration was useless. To attempt to settle this question, there was built in the Hospital of the Rockefeller Institute a chamber in which the oxygen content of the air could be regulated, and in which patients suffering from pneumonia could be treated. The results in the relief of cyanosis were so striking that since then numerous chambers in various hospitals have been constructed, and many other devices for increasing the oxygen content of the air breathed by the patient have been designed.

So far as simplicity of operation, comfort of the patient, and convenience as regards nursing are concerned, there can be no doubt that the chamber is *par excellence* the method of choice. But the initial expense is great, and chambers are not generally available. Tents have now been perfected so that in them it is possible to maintain a constant atmosphere at an even temperature almost as satisfactorily as in the oxygen chamber. The nasal catheter method is useful, but is to be recommended only when no other method is available. Recently a very ingenious and simple method of administering oxygen has been devised by Dr. Burgess of Providence. This consists merely of a box, open at the top, lined on the sides and bottom by a rubber bag attached by clamps to the upper edges of the box. At the front is an opening in the rubber bag through which the head is thrust, the edges of the opening fitting tightly about the neck. In the bag near the bottom are openings for tubes through which oxygen is allowed to flow continuously. The oxygen diffuses only slowly upward, so that with a flow of four to six liters per minute the air in the bag at the level of the patient's mouth and nose can be kept constantly at 40 to 50 per cent of oxygen. With a satisfactory cooling system, the apparatus can be employed continuously without discomfort to the patient.

In our earlier employment of the oxygen chamber we determined whether a patient should be treated by this method or not by making actual measurements of the degree of oxygen unsaturation in the arterial blood. It has been found, however, that the degree of cyanosis present is a sufficiently accurate indicator.

Our custom is to maintain an atmosphere in the chamber containing 40 to 50 per cent oxygen, usually 40 per cent. Others advise higher concentrations, but it must always be borne in mind that very high oxygen atmospheres are toxic. There seems little use in increasing the oxygen to a level higher than that necessary to relieve the cyanosis. It is not likely that placing the patient in the chamber for short periods of time is of any value. Having

once placed a patient in the chamber, it is our usual custom to keep him there until the acute intoxication is over, and then to bring about the change to usual atmospheric conditions very gradually

It is very difficult to evaluate the actual benefit derived from the use of oxygen. While, by an occasional patient, much subjective relief is obtained, in most instances this is not evident. The immediate effect on the character and frequency of respirations is not so great as certain of the reports would lead us to expect. What the effect may be on the final outcome cannot be stated at present with any degree of accuracy. Contrary to the statements of other enthusiastic observers, I can only say that our mortality in cases not treated with serum has not notably diminished since the introduction of the oxygen chamber. Nevertheless, we should feel greatly handicapped if we lacked facilities for supplying oxygen to patients with cyanosis.

SODIUM CHLORIDE

Another physiological alteration in patients with pneumonia is a decreased excretion of chlorides in the urine and a diminution of the chloride content of the blood plasma. From time to time during the past 25 years, papers have appeared dealing with the saline treatment of lobar pneumonia. Recently attention has been drawn to the fact that both in lobar pneumonia and in pyloric or high intestinal obstruction the chloride content of the serum is decreased. It has been found that the administration of large amounts of salt-containing fluid to patients with obstruction or to dogs in which the condition has been produced experimentally results in a marked decrease in the intoxication and prolongation of life, and this has been used as an argument in favor of administering sodium chloride to patients with pneumonia. It is doubtful, however, whether there is justification for drawing this analogy too closely. It has been shown that the loss of chlorides in obstruction is directly related to the vomiting of the high chloride-containing gastric contents. The loss may be enormous, and loss in water may be correspondingly great. Under these conditions it is not surprising that replacement of the salt and water may be very beneficial.

On the other hand, the diminution of chlorides in the blood in pneumonia is minimal compared with that occurring in obstruction. Moreover, in patients that have been given 15 to 30 gm of sodium chloride per day, there is little evidence that the chloride content of the blood has been increased to normal amounts. Certain writers are very enthusiastic about this form of therapy. Other good observers are more cautious, but still believe advantageous results are obtained. Influenced by these opinions, we have given certain of our patients moderate doses of sodium chloride daily and have thought that, in some instances, abdominal distention was thereby diminished, and some decrease of the symptoms of intoxication was observed. It will require much wider experience definitely to decide these questions. One of Sunderman's patients developed subcutaneous edema

when receiving 15 to 30 gm per day, and other observers have noted the occurrence of pulmonary edema. Large doses should, therefore, be avoided. Our patients have received not more than 10 to 12 gm, usually 5 to 8 gm, in addition to that in the diet daily. The salt is given in capsules. Frequently nausea and vomiting result. McCann recommends that in serious cases 10 to 15 per cent NaCl solution may be given intravenously. Thirst is frequently increased following the administration of sodium chloride, and therefore the administration of fluids is facilitated. In so far, at least, the method is useful. In all cases of pneumonia, the attempt should be made to administer at least 3,000 c c of fluid daily. If the patient will not or cannot take this amount, it may be given in the form of normal salt solution intravenously. Additional calories may also be given by adding glucose to the salt solution.

At the present time the administration of sodium chloride to pneumonia patients should be considered to be in an experimental stage, and the basis for this form of therapy largely empiric. One must always remember that modification of physiological alterations present in disease does not necessarily increase the patient's chances of recovery. Most of us remember when antipyretic drugs were in their heyday. Today, fever is being produced artificially in attempts to cure certain infectious diseases.

DIGITALIS

Much has been written about circulatory disturbances and about the failing heart in pneumonia. Contrary to the usual opinion, my own experience has led to the view that the early intoxication in pneumonia rarely manifests itself by injury to the heart, and that circulatory inefficiency is usually a late manifestation of the disease, occurring at a stage in which drugs can be of little value. Most patients die in pneumonia, not from cardiac failure, but from disturbances in respiration. Observation of the character of the breathing (frequently gasping and shallow, with laboring of the muscles of respiration) gives much better prognostic information than measuring the blood pressure. Of course, in the later stages of pneumonia, gradual lowering of diastolic pressure with loss of tone in the peripheral vessels and signs of cardiac dilatation do occur.

The question of the employment of digitalis in pneumonia is not yet entirely settled. In 1916, on account of the considerable number of pneumonia patients showing cardiac irregularities, and because of the known danger of attempting to digitalize the heart rapidly, the method of giving all pneumonia patients moderate doses of digitalis was introduced into our clinic. In 1930, however, Niles and Wyckoff reported that in a large series of cases treated with digitalis, the mortality was considerably higher than in a corresponding series of cases receiving no digitalis. In the light of this experience, Cohn and Lewis carefully reviewed all our cases. The conclusion reached was that giving digitalis did not seem to influence the course of the disease. As a result of these studies we have discontinued the

routine use of digitalis, employing it only under conditions, such as auricular fibrillation, where it would ordinarily be employed, even though no pneumonia were present, and then in exactly the same manner

In cases where there is a progressive fall of the blood pressure, it is our custom now to rely on intravenous infusions of normal salt solution with, if necessary, injections of ephedrine

It is needless to discuss here the other drugs that have been used in the past to stimulate the heart, frequently as a routine, before any signs of cardiac weakness have appeared—caffeine, strychnine, camphorated oil Today I think there are few advocates of this form of therapy

QUININE AND ALCOHOL

Besides these measures, intended to relieve certain symptoms and to overcome definite physiological alterations, numerous methods have been proposed which are supposed to have a definite action on the infectious process, the nature of the action, however, not being understood at present, or only explained by theoretical considerations Ever since pneumonia was first recognized, modes of treatment have appeared, flourished for a time, and then disappeared One has only to recall the vogue for blood-letting which flourished in waves from the time of Hippocrates, had an enormous vogue in the seventeenth century, and was still recommended and even somewhat widely employed in my own early medical days There were periods in which failure to bleed and actively purge with tartar emetic was ground for malpractice suits

Certain drugs, as alcohol and quinine, have been thought to have a specific action in this disease, and are still employed by certain physicians I have had little experience with the intensive use of quinine, but early in my medical life saw patients treated routinely with large doses of alcohol My recollections of this experience are not pleasant It is generally held that in alcoholic patients it is wise not to discontinue its use completely, and this seems sound and is the custom in our clinic

Other measures which have a vogue today and concerning the value of which the evidence is more or less conflicting, are diathermy and artificial pneumothorax

DIATHERMY

Several years ago, influenced by the reported favorable results from the use of diathermy, Binger and Christie in our clinic carried on studies with the idea of determining its value During the passage of the diathermy current they made direct measurements of the temperature which developed within the lungs in dogs, both in the lungs of normal dogs and in those which were the seat of a pneumonic consolidation It was found that in normal lungs in no instance was it possible to demonstrate any considerable amount of local heating, the explanation being that the lungs represent an excellent watercooled system, and that the intact pulmonary circulation

prevents any considerable degree of local heating. In consolidated lungs of dogs, probably because of the disturbed circulation, it was possible to increase the local heating slightly but not more than one or two degrees. In three pneumonia patients direct measurements of the lung temperature were made by the aid of thermocouples enclosed in an ordinary Luer needle, which was inserted directly into the consolidated lung. In none of these patients was there an appreciable rise in lung temperature during or after exposure to the diathermy current.

In the light of these studies no further clinical use has been made by us of this method of treatment. One hesitates to state categorically that this method has no value. We grow cautious with experience. One can only say that it is not based on experimental or clinical studies that appear to be sound. Even though it were possible to raise the temperature within the lung, it would not necessarily follow that the results would be beneficial.

ARTIFICIAL PNEUMOTHORAX

Although artificial pneumothorax as a therapeutic procedure was carried out in a few cases of pneumonia in 1919 to 1922, the method was not employed to any considerable extent until within the past two years. The chief justification for its employment is that offered by Friedman, who stated that by the collapse of the lung a state of immobility or rest is produced which diminishes the absorption of toxic products, and promotes healing. At the same time the inflamed pleural surfaces are separated, thereby pain is relieved, enabling the patient to breathe more deeply and also to obtain mental and physical rest.

Most of the clinical reports, so far, have concerned small numbers of cases, and usually only moderate amounts of air were injected. The most extensive and careful study has been that of Blake in 42 cases. He has drawn attention to the fact that to obtain immobility of the lung it is necessary to inject sufficient air to produce complete collapse. He studied his cases by roentgen-ray examinations and found that the amount of air necessary to produce complete collapse varied greatly in different patients, and could not be predicted, but usually varied from 1800 c c to 2400 c c. From a study of his cases it is difficult to judge whether or not the procedure had a favorable effect on the outcome. He rightly avoids drawing conclusions from the mortality rate in such a limited number of cases. However, 10 of the 42 patients died. There is, on the other hand, no evidence that the treatment was harmful. In only one of the cases treated before 72 hours after onset did spread to the opposite lung occur. He speaks of the excellent therapeutic results in the early cases without interfering adhesions, but only 10 of his cases belonged in this category and he concludes that "the use of this operation as a therapeutic measure in selected cases is worthy of further trial."

In our clinic at the Rockefeller Institute, a small number of cases has been treated by this method, and a clinical report on nine thoroughly studied

cases has been made by Abernethy, Horsfall, and MacLeod. Since this report, 13 further cases have been treated, making 22 in all.

Confirming Blake's observations, it was found that large amounts of air were necessary to produce collapse of the lung and immobilization. Pleural pain was relieved, but in many instances where large amounts of air were injected there developed dull, aching substernal pain that at times was as distressing as the sticky pleural pain had been. Moreover, in some of these cases, there occurred an increase in the dyspnea, tachypnea and cyanosis. While no permanent harmful results could be demonstrated, the procedure could not be shown to exert any favorable influence on the course of the disease. In the more recently treated patients, only small amounts of air, sufficient to separate the pleural surfaces, have been injected, and in most instances the relief of pain has been definite.

Although apparently so far no serious results have followed the production of pneumothorax in patients with pneumonia, the method is not without its dangers. In two of our cases apparently rupture of the lung occurred, with the development of very high intrapleural pressure and widespread subcutaneous emphysema. Both of these patients were subjects of chronic pulmonary emphysema and the operation should probably not be undertaken in such persons. In five of our nine cases treated by complete collapse, there developed an accumulation of fluid in the chest, but in only two was it sufficient in amount to require aspiration. While empyema has developed in a number of the reported cases, this has not occurred as frequently as might have been anticipated.

While carrying out this procedure in pneumonia is not a serious or difficult operation, it is not one to be lightly undertaken by anyone who has had no previous experience with the technic of artificial pneumothorax.

CONCLUSIONS

From this brief review it seems evident that the only form of specific therapy proved to be useful and available at present is serum treatment in Type I pneumonia. Etiologic diagnosis should be made as early as possible and treatment started without delay. Care should be taken to have good serum and it should be administered in large amounts and its use continued until recovery is evident. Certain measures, such as the administration of oxygen and of sodium chloride, may be useful in overcoming pathological variations in the body mechanism.

The value of artificial pneumothorax awaits further study. At present its usefulness seems to consist in the relief of pain rather than in any effect on the infectious process. Finally, it should be stated that, while the solution of the pneumonia problem has not been reached, some advance has been made in the past twenty-five years. Not the least important part of that advance has consisted in the increase of knowledge concerning the nature of the disease and of the natural mode of recovery. The accrued knowledge should lead to acceleration of progress in the development of methods of treatment and cure.

THE RÔLE OF THE PERSONALITY IN PSYCHOTHERAPEUTICS

By AUSTEN FOX RIGGS, M D , F A C P , and HORACE K. RICHARDSON,
M D , F A C P , *Stockbridge, Massachusetts*

A psychoneurosis is an involuntary and automatic disorder of normal people, based on hypersensitiveness and the relative imbalance of instincts, causing inner conflict between instinctive forces and adult, intelligent strivings and ideals. Some outward maladaptation to life manifests itself by typical symptomatology in the vegetative, somatic, emotional or intellectual fields, thereby functioning as a compromise between the demands of the instinctive forces and the higher intellectual and ethical aims, and as a protective mechanism against whatever is painful and unacceptable emotionally and intellectually. The particular form of neurosis which develops is determined by the relative composition of individuality and environmental experience.

The importance of the situation in the origin and development of the psychoneuroses has been forcefully and accurately demonstrated. While it is a recognized fact that certain types of situations in life are common to the origin of all cases of nervous illness, they are recognized as the precipitating causes only. They constitute an extremely important factor in the development of the various types of maladaptation, however, and may give the key to an understanding of the nature of the case, be the determinants of the ultimate prognosis, and indicate the pattern of the therapeutic approach. We believe, however, that the fundamental causes of the psychoneuroses lie within the individual himself in the form of a specific hypersensitiveness to sensation or to emotion, or to both.

The treatment of the psychoneuroses consists of three major efforts, namely (1) to disclose to the patient the original causes of this hypersensitiveness, including those of a basic constitutional nature, (2) to assist him in the development of insight into the origin, nature and function of the maladaptive reactions, (3) to use this understanding of the fundamental qualities of his personality as the foundation upon which to erect a more efficient plan of living. We believe that the origins of the psychoneuroses lie in the phylogenetic and ontogenetic development of the structure of the personality, and therefore constitute the essential guide to the therapeutic approach in each case. Hence, we shall devote the remainder of this paper to a consideration of this aspect of psychotherapeutics.

At the outset we must presume the acceptance of the principle of psychological integration in contradistinction to the pedantic attitude of parallelism, which implies a theory that mind and body "accompany each other

* Presented at the Detroit meeting of the American College of Physicians, March 3, 1936

but are not causally related." For many centuries man looked upon himself in terms of biological fragmentation. Isolated manifestations of his personality occupied his attention for certain periods of time to the temporary exclusion of all others. Sherrington, in 1906, brought out his inspiring work on the integrative action of the nervous system and forever changed this attitude of incompleteness. Adolf Meyer accomplished an even more useful piece of work when he emphasized the pragmatic significance of this principle of integration in the higher mental functions and between the various physiological and psychological levels. This implication not only assumes a relationship of structure, but includes as well a unity of action even more closely organized than the structural systems themselves. There is an interdependence and synthesis of function and action that frequently transcends our knowledge of nervous system localization, and even in the presence of disease processes and disorders of function, we still witness the evidence of an organized whole. This often persists in spite of partial disintegration in certain parts of the organism, either structural or functional. In spite of the great individual differences among various people, we always find this fundamental principle of integration as the major factor in the total organization of the human personality. The ideal of mental health is based upon this unity of the personality. In any therapeutic effort, therefore, this ideal is the basis for the development of an understanding of disintegration, as well as integration, and until the former is investigated subjectively and understood by the patient, the subsequent steps of psychotherapeutic effort leading to integration cannot be comprehended, and their value is lost to the patient. Unless each of the antecedent steps in this synthesis is fully understood by the patient himself there will be a succession of corresponding faults in the later stages of his understanding, and in his ability to synthesize all of its factors. We believe, then, that a review of the biological and developmental factors of his personality constitutes the first and most fundamental parts of the plan of reeducation.

There have been many overlapping classifications and descriptions of personality attempted. No two psychologists would agree as to its basic structure, its exact definition or its fundamental characteristics or distinctions. Study and observation by many individuals have resulted in an encyclopedic accumulation of facts and theories relative to the personality and its reactions and expressions. Frequently the terms "personality," "individuality" and "character" are confused and used indiscriminately.

Jung's concept of introvert and extrovert personality is altogether too restricted, and does not appear to give consideration to immediate antecedents. Kretschmer's plan of pyknic and asthenic types, although based upon biological and constitutional fundamentals, involves a typing of personality rather than an explanation of structure. It implies a consideration of character. Character is not a fundamental part of personality, it is an expression of it. Freud, aside from his overaccentuation of sex and the rôle of the unconscious, came closer to what we believe to be the truth in his

"Id-Ego-Super-Ego" idea, but he apparently minimized the essentially organic or physical elements in personality. Adler, in his individual psychology, is altogether too stereotyped and teleological, and, like Jung, disregards immediate antecedent circumstances. There are many other theories, but in our opinion they are more or less impractical because they do not carry causal implications.

It is our belief that the most useful and accurate concept of the personality structure is that based upon the theory of the psychobiological development of the animal kingdom from its beginning to the present. We believe that each individual personality is made up of the end-results of development, the residuals of growth and experience, integrated into certain actual and potential constituents which express themselves in four predictable types of specific reaction. These reaction types, the reflex, the instinctive, the intelligent and the ideal, are based on four developmental neurological levels of the nervous system. These four levels of reaction represent four major developmental epochs of the entire animal kingdom from the amoeba to man, and therefore explain the purely biological foundation of the concept. They are repeated in the development of the individual from birth to maturity, and supply an adequate background for understanding both the mature and the immature aspects of personality. They explain the phenomena of personality disintegration and retardation, and give a foundation for comprehending the antecedents of individuality and character. These reactions include the physical, emotional, mental and moral dynamic forces of life, which vary in relative strength in each individual. They undergo many specific modifications through certain conditioning influences of life from childhood onwards, and thus give us a basis for comprehending individuality and furnish adequate explanation for the antecedents and motivations of all types of psychoneurotic maladaptation. When these reactions are considered in the light of individual hypersensitiveness, they explain the degree of the dynamic responses. This concept not only satisfies the biological point of view, but has proved satisfactory in the understanding of the origins and determinants of psychoneurotic maladaptation, and in addition furnishes a convincing foundation upon which to erect a successful system of psychotherapeutics. It stands the practical test of experience. This concept bears a certain superficial resemblance to Freud's more recently developed figure of "Id-Ego-Super-Ego," which, however, is more apparent than real. Any question of its priority is settled for all time by the relative dates of publication. It was published in 1912, while Freud issued his book in 1921.

The first of these developmental levels, the reflex, represents the lowest type of biological adaptation as implied in the functions of the primitive brain stem, a stage of biological growth when the neurological elements were relatively simple. It is a purely physical or somatic type of response and does not imply a "mental" reaction as commonly understood. This type of response implies all those primitive, non-affective responses which occur outside of awareness, and which, through the process of conditioning and

repetition, have become incorporated into automatic neurologically determined functions. In this evolutionary stage there had not yet appeared any of the so-called higher functions of feeling or thinking. At this level are found those phylogenous influences commonly included in Jung's concept of "the collective unconscious." This primitive structure in man is represented in general by the spinal cord and the medulla. It is at this level that the constitutionally determined element of sensitiveness first appears. An understanding of the elementary functions and expressions of this level of reaction upon the part of the patient is necessary, and the development of this understanding is one of the first steps in the therapeutic excursion.

The second type of reaction is due to the development of the next higher level of neurological structure, the diencephalon, which, in the words of Tilney and Riley, "gives rise to the thalamus, the hypothalamus, the epithalamus and the metathalamus." When this region in the brain developed, there arose a new type of reaction known as the "instinctive." These instinctive tendencies are the raw forces at the bottom of man's behavior, so to speak. They function from birth to death. Some of these forces have to do principally with the individual's survival, with his security as an individual. Others function as forces which insure the procreation of the race, others for the welfare of the race en masse. Each instinctive reaction is as it is because of the individual's inherent structure and the functional organization of that structure. Man is timid and pugnacious, socially inclined, hungry, sexually susceptible because he is built that way and organized that way—born to react that way. But each man is apparently born unequal so far as the relative strength of the instinctive tendencies is concerned. Some men are "naturally" more pugnacious than timid, some more dependent on their fellow man, some more self-assertive than others and so forth. Many of these relative differences are observable at birth or very soon after, in short, before environmental experience could reasonably be supposed to have modified the raw material to any great extent.

Instinctive reaction is not, however, a simple mechanical reflex even in its primordial raw form. It involves the whole creature, his whole biophysical organization, together with many complex reflexes and is accompanied by much activity that does not necessarily appear on the surface, as has been ably demonstrated by Cannon. For instance, if the instinctive tendency to self-protection is aroused, there is a quick mobilization of all the physiological forces appropriate to escape. Almost at once the animal, be he man or rabbit, finds himself in the best possible condition for flight. The muscles of locomotion have become tensed, the circulation carries to them blood freshly loaded by the endocrine glands with material for the most effective and efficient action. Respiration is doing its part to keep the blood stream thoroughly oxygenated. The gastrointestinal tract's activities are throttled down to a condition of relative paralysis. Other physiological changes have taken place, all functioning in the same direction, until the creature is in an ideal state for the instinctive action of escape to take place.

While all this is going on, it is of course inevitable that the creature must be conscious of at least a large part of these changes. He is no longer comfortable, in fact he is distinctly uncomfortable. He may be aware of his dry mouth, of his rapid heart beat, of his trembling, tense muscles, but even if he is not aware of these specific items, he is at least aware of the sum total of the changes that have occurred in his bodily sensations, so that he *feels* a painfulness and at the same time as part of that uncomfortable feeling, a strong desire to escape, to discharge that mobilized energy and to rid himself of the discomfort as fast as possible. In short, when the instinct of escape is aroused, the creature is not only mobilized for escape, but *feels* that mobilization as a strong emotion accompanied by an intense desire to flee.

Thus an instinctive reaction may be said to have three parts just as the simple reflexes have three parts—the sensory, the central adaptor and the expressor or motor part. Each instinct can also be said to be accompanied by its own appropriate emotion which is either painful to some degree or pleasant to some degree, and which besides its pleasure or pain element has a second strong motivating force within it, namely, the desire to escape from or approach the object which has aroused it.

The instinctive make-up of an individual is the second structural element of his personality and individuality. Therefore, to understand him it is necessary to gauge as nearly as possible what the relative strength of instinctive forces in his inherent makeup may be. Is he more pugnacious than timid? Has he a relatively strong or weak social drive? Is he more self-assertive or more retiring than self-important? Has he a relatively strong or weak sex drive? Is he more or less suggestible than the average? By suggestible is meant the degree to which he is liable to the uncritical acceptance of ideas. It is an instinct-like quality present to some degree in everyone, usually greater in youth than in adult life, and varying in regard to any subject in inverse ratio to the amount of the individual's knowledge of that subject.

The development of insight upon the part of the patient into the nature of these instinctive reactions, especially those that have contributed largely to the origin of his own conflicts, is the second logical step in the development of the therapeutic teaching.

The third type of biologically determined reaction is the intelligent. It came about as the result of the further development of the telencephalon or end brain. Growth in this part of the central nervous system brought new capacities and abilities, a new function and a new type of reaction to the various stimuli of life. Just what intelligence is we do not know. The word is used very widely and as loosely as most psychological terms. Let us limit the meaning for our present use to its functional significance rather than to attempt a definition. Let intelligence mean the ability to understand, to comprehend whatever our senses bring to us and to judge of its significance. Let us add to understanding and judgment one other related sub-

function, namely, choice, which is the executive function of intelligence, and then the description will be sufficient for our present purpose

Obviously individuals vary widely in regard to the quality of intelligence they possess. Here again men are born unequal, some extremely well endowed, some with only an average endowment, and others poverty-stricken from birth. From the quantitative point of view alone then, intelligence is one of the fundamental variants determining the individuality. This characteristic varies greatly within the normal, but more in quality than in quantity. It would seem, in short, that people differ from each other even more markedly in the specific type of intelligence they have than in just how much of that master function they possess. One need only mention the vast differences among children, the mechanically minded, those who take to mathematics with marked ease, while others are "born linguists," to appreciate how important a variant within the normal this qualitative specificity of intelligence is in the equation of individuality.

These variations in the fundamental and functional, the inherent and acquired intelligence are of at least as great import to the understanding of any individual as the variations of instinctive make-up, for by virtue of the former his mode of adaptation to his world will be very largely determined.

In the ability to understand, to judge of the significance of things and to exercise choice, is observed the great adaptive control of all the foregoing primordial forces. It is that which enables us to understand our environment, our relation thereto, and last but not least, to choose among all the possible plans of action the one most likely to give us the results we desire. It is this faculty par excellence which constitutes man's ability to make his adaptation purposive, and this raises it from animal reaction to human behavior.

Finally there comes the fourth or highest level of the adaptive machine as represented neurologically by the growth and development of the neopallium. This level is known as the ethical and it is here that the most difficult integration takes place. Man's demand for the specific form of satisfaction and happiness which ethical conduct engenders seems to be a genuine biological development. Is it not indeed this very demand in each individual which makes civilization a biological necessity? In early time the instinct of self-protection underwent modification when man began to live in groups and the safety of the group had to take precedence over the survival of the individual as each man's objective, and thus simple society became a sort of mutual protective association where each individual was classified according to his material value to the group. A sense of individual responsibility toward every other member developed, probably the expression of a strong instinctive force released by the absence of the necessity for self-protection, which grew as part of the progress of society toward civilization. This desire to protect, this responsibility for the welfare of the other fellow no doubt spread from its earlier exclusive application to

members of the individual's own group, until it included those of other groups and finally, as an ethical idea, became all-embracing

However, the ability of the individual human being to function ethically is apparently acquired through training, example, education and other forms of experience, for although there is an inherent drive in this direction, the acquirement of it takes many years, beginning in infancy and continuing into old age, at least to a diminishing degree. It is upon this level that the unified energies of man come to fruition in the form of purposive striving and it is here that man erects his philosophy of life

An item which affects individuality very definitely and which varies greatly even within the normal is mood. Let it be understood that by mood is meant the general tidal level of affective activities, the height or depth of the feeling level. The top of the tide represents the mood of exaltation and a full moon flood tide, transcending the normal, will represent manic elation. The ebb tide, on the other hand, pictures gloominess, blues, and the extreme ebb, beyond the normal, would represent the depressed phase, the melancholia of a manic depressive episode. But well within the normal there are mood swings both up and down sufficiently marked to affect not only feeling but thought and action as well. Normal people vary from each other in the degree to which they are subject to mood swings and also as to whether these swings are habitually up or habitually down, and as such mood swings tend invariably to affect both thinking and acting, they can neither be ignored in understanding an individuality nor neglected when dealing with a person's difficulties in adaptation.

There is one all-qualifying item in the equation of individuality which, according to our present formulations, comes neither under intelligence nor instinct, but, nevertheless, has to do with both and with every other characteristic of every human being, and that is temperament. This word has been used so freely and so carelessly not only in common parlance by the man in the street, but also in psychological literature that it may connote anything from the sum total of human characteristics "to an overworked alibi for being dirty, careless and never paying one's bills." So here again we must limit the meaning of the term to something definitive and practical. In this case let temperament equal sensitivity and, to be more specific, let it equal that particular degree of sensitiveness to the painful or pleasurable in sensation and emotion, thought or mood possessed by an individual. Even shortly after birth it can be observed how infants vary in acuity and completeness of reaction to stimuli both internal and external. Even babies manifest a degree of sensitiveness so that "he who runs may read." It is almost equally obvious in adults in spite of the modifying influence of experience and training, for in them that sensitiveness to the pain-pleasure element in experience has already become highly specialized, highly specific. In short, through experience this sensitiveness becomes specific to the instinct or instincts which are inherently relatively overactive or which have become so through experience. Therefore, the finished product will manifest his

sensitiveness in particular and often easily observable directions. This sensitiveness is a very real thing physiologically as well as mentally. For instance, a hypersensitive person who is at the same time more timid than pugnacious not only needs more courage to achieve even ordinary aims, but will show his sensitiveness to fear not only in the necessity of more than ordinary courage but in the aggravations of the physiological reactions characteristic of fear. These may manifest themselves in disturbances of the gastrointestinal tract or of the heart's action, by sweating or by blushing and blanching, or in short, by undue disturbance of any or all of the functions under the dominion of the sympathetic system.

Obviously the effect of variation in this characteristic upon the individuality as well as upon the technic of the person's adaptation may well be striking. The part that it plays in normal life, its functions as an asset, as well as its rôle in psychoneurotic maladaptation, its liability aspect, is one of the main concerns of psychotherapeutic treatment.

To recapitulate briefly, the component parts of personality and their respective neurological levels are

First, the level of vital reflex under the dominion of the medulla.

Second, the primal inherent forces called instinctive in which we follow very roughly McDougall's classification—instincts which serve self and those which serve race and species, represented on the neurological level by the thalamic region of the brain.

Third, intelligence, that characteristic which modifies or adapts the primal forces to a wider, more elastic and diversified use, represented neurologically by the fore-brain.

Fourth, the super-intelligent or ethical level, represented by the latest and most complex development of the fore-brain, particularly by the frontal lobes.

Finally, to complete the picture of individuality, we must include mood, temperamental-sensitivity, items which directly qualify the primal forces, as well as intelligence, by affecting the quality and intensity of their action.

These are the variables in the human equation which in their reaction to one another and through their organization as a whole constitute the bio-psychological entity, the individual, who in ways that are characteristic of the race, on the one hand, and of himself individually on the other, reacts to his environment and to which the environment reacts.

These four levels of biological development, which represent the evolution of the adaptive processes of the animal kingdom, are repeated in the growth of each individual. They must be studied in regular order and thoroughly understood by the patient before he can comprehend the various factors that have preceded his maladaptations.

At birth this machine is imperfectly developed and immature, and, therefore, functions only in part. The process of maturation is determined and affected largely by the nature and character of the environmental influences, i.e. the stresses and disciplines which surround the growing child. On his

way toward maturity, the individual may undergo certain experiences, real or imagined, which tend to condition or modify him to fix his reactions at definite chronological levels and often relegate many of them to the unaware regions of consciousness. It is by this process that the useful experiences of the individual become stored away and made automatic, thus relieving the intelligence of the necessity for repeatedly thinking out solutions for the many new situations that arise in his daily life. It also frees the intelligence and makes it available for use in new experiences and for making adjustments on the purposive plane, but it is also during this process that immature emotional values may be given, more or less permanently, to reactions, which reappear in adult life as though they represented present experiences. Frequently these experiences represent conflicts between the various reaction-levels of the personality and furnish the basis for the origins of the psychoneuroses. Recent environmental situations may reactivate those old emotional values through association and thus contribute to the causes of the maladaptive reactions. Thus it becomes necessary that the individual should possess insight into these motivations and the development of this insight is an important factor in an effective therapeutic effort.

At birth the normal infant is equipped with a potential capacity for the development of all four of these levels of adaptation. Actually he is largely a mass of reflex reactions, many associational tracts are not yet myelinated and he remains in this condition for a relatively long period after his birth. He is the most dependent creature on earth. He cannot express his needs or his desires in the language of his environment. He cannot move toward the sources of his food supply. He would die of starvation and exposure were it not for the assistance given him in this first stage of his development. He is non-logical because intelligence has not yet developed. He is non-moral, having no group consciousness, and he is completely egocentric and as yet has no concept of "I" or "You". The security of food and protection from the elements are his only needs and are supplied by those around him. Later his psychological needs are furnished by the attention, love and approval of the individuals who constitute the parental group. Because of his immaturity and inability to comply with the laws and customs of this group, the child lives in a world of criticism, admonition and discipline. The first words usually spoken to an infant after the excitement of his arrival has passed is the negative "No! No! Mustn't do that!" Later, these attitudes of constant correction upon the part of the adults (one author calls them "Giants") are frequently unconsciously interpreted as a withdrawal of parental love, or as a possible threat to this love, unless they are balanced by the opposite attitudes. Because of his nature the child cannot mature uniformly and completely without this affection as expressed in approval. He therefore attempts to modify his own demands and conduct, so as to comply with the arbitrary demands of the environment in order to obtain it, in spite of his own wish to act in the opposite manner. He senses, sooner or later, that cooperation with these

external demands brings him the pleasure which the attitude of approval upon the part of the parent excites within him. Parental attitudes, then, become the first and most important factor in conditioning the child's early psychological existence.

As time goes on and the child grows older the instincts become more and more prominent and determine in an increasing degree the motivations of his conduct. As the instinctive desires, needs and demands for gratification become stronger, the greater becomes the conflict between the child and his environment, and the more difficult becomes the solution of the problem of the socializing of his instinctive forces. Eventually the child begins to comprehend the meaning of the contrary attitudes of the parents, but because of the power of the non-logical and non-moral instincts he is bound to have a certain degree of difficulty in complying with them. We tend to forget that he is not just a small adult and expect altogether too much of him. He is but an immature child and he does not yet possess the adaptive machine of an adult. The result of unwise parental attitudes is repression. The more severe the parental authority and the more sensitive the child, the more numerous and deeper become the repressions, or the more violent are the rebellion and resentment against parental authority. The more exaggerated and persistent the authority, the more the repressions become charged with overdetermined emotional values.

Because of the rapidity with which each new experience comes to the child, and the necessity for learning quickly the difficult business of adaptation, there are many experiences which are thrust into the realm of unawareness in an unfinished condition and partly or wholly forgotten, although the emotional force attached to them may remain active. The child mind cannot make accurate interpretations or determine correct values in many of these new experiences, and consequently these are stored up in his mind with fictitious values attached to them. These overdetermined and little understood emotional experiences may lie in the unaware region of his consciousness for years in an unfinished and unresolved state and may thus continue to furnish the motives for thoughts and conduct which are frequently inexplicable to outsiders as well as to the individual himself.

There comes a time in the stages of development when an entirely new element makes its appearance in the growth of the personality. Its arrival is not as abrupt as this statement might imply for it makes its appearance gradually and, at first, in minor, simple manifestations. It is the development of the ego or selfhood and occurs at the level of intelligence and at about the same time as the aggressive instincts become more prominent. Self and the awareness of self undergo accentuation, but he also becomes aware of himself not only in terms of the drive of self-importance and self-expression but also as an individual striving for the ethical objectives in his relationship with others. He begins to identify himself with his own kind and tries to act in the manner of an independent adult.

Soon the world of the child enlarges, and he finds himself more or less

on his own in contact with people both young and old outside of his own immediate family group. The child is at first confused by the apparent disagreement between his formerly unquestioned parental authority and the actual facts of life as he now observes them. Here before his eyes is another child doing the very things prohibited by his own parents, and escaping the punishment which he had learned to expect. What does he do? He begins, with much trepidation, to use his newly acquired ego and its correlative intelligence. He begins to experiment. He begins to use his new aggression. To his amazement he discovers that he also escapes the consequences predicted by his parents. Thus he goes through a period of disillusionment and reevaluation. He discovers that certain laws set up by the parents are not universally accepted and that certain parental attitudes and opinions are not necessarily correct. He discovers that in fact they are frequently met with ridicule, disrespect and complete rejection by his fellows. As the result of these experiences, he modifies the ideals set before him by his parents and builds up ideals and principles of his own. As he slowly becomes wiser through experience, he builds his own authority and forms his own opinions. He gradually learns to renounce the gratification of obedience to parental authority, and becomes less and less dependent upon it for his inner comfort and satisfaction. But regardless of how old he becomes and the degree of wisdom to which he attains or the extent of his sophistication he never becomes completely mature emotionally. There is no such object in nature as an adult who is completely mature emotionally. The effects of many forgotten admonitions and criticisms in childhood, of prohibited acts, phantasies and thoughts of the immature period may still be present in the unaware consciousness of the adult, influencing thought and conduct and consequently affecting the habit patterns of character. These conditioning influences of childhood are perhaps the only important environmental factors, for the specific way in which the individual reacts to them is due primarily to his particular constitutional make-up, whether he meets criticism and discipline with open and successful rebellion or retires to his corner whipped and assumes the rôle of the overgood child or becomes a nervous, irritable, frightened person depends first upon the degree of sensitiveness with which he was born and his inherent instinctive make-up, and only lastly upon the stimuli arising from the environment.

Therefore the physician cannot be content in unearthing ancient conflicts between conscience and instinct but must discover and help his patient to understand what inherent qualities of his own personality caused him to react to these common difficulties in such a way as to contribute to the formation of a psychoneurosis.

We have said that the treatment of the psychoneuroses consists of three major efforts.

- 1 To disclose to the patient the original causes of his hypersensitiveness, including those of a basic constitutional nature, if possible.

2 To assist him in the development of insight into the origins, the nature and the function of the maladaptive reactions

3 To use this understanding of the fundamental qualities of his personality as the foundation upon which to erect a more efficient plan of living in the future

Studying the patient according to the method suggested in this paper, and with the knowledge gained from physical examinations, laboratory studies and careful survey of the patient's heredity, etc., we are frequently able to find and disclose to the patient his inherent hypersensitiveness and the specific nature that it has acquired. This fulfills item one of the psychotherapeutic program.

In taking the patient through his own growing-up processes by helping him to give the fullest possible history including an account of parental, social, educational, religious and other influences, supplemented if need be by controlled association, we endeavor to find the sources of his difficulties in adaptation, including such overloaded emotional values as may be associated therewith. This should result in the gradual development of insight into the origins of his troubles. As he gains perception he becomes aware of the real nature of his illness, and finally is able to realize that his nervous condition is functioning as a means of defense or escape. Ultimately he becomes aware of the fact that his illness is the result of his own hypersensitive reactions to the circumstances of the environment rather than that the environmental situations are more powerful than his personality and his ability to handle and solve them. This completes the second state of reeducation.

Finally, the third effort in the reeducational process is begun. In this stage the patient uses the knowledge he has gained of the elements which constitute his personality. He has already developed an intimate knowledge of those elements of his personality which have been responsible for causing his neurosis. With the help of the patient and by thinking *with* him in place of thinking *for* him more practical concepts of life are built up and better planes for a balanced life can be formulated.

When the period of intensive reeducation has been completed and there has been some incidental but important practice in the daily application of the principles taught, the patient is discharged and returned to his own environment for a trial trip. Following his discharge, close contact is maintained in order that his progress may be supervised, which is accomplished by one or more return visits of brief duration for review and advice.

TOTAL LEUKOCYTE COUNTS IN HUMAN BLOOD DURING PREGNANCY ¹

By J B CAREY, M D , F A C P , and J C LITZENBERG,† M D , F A C S ,
Minneapolis, Minnesota

VIRCHOW spoke of a physiologic leukocytosis of pregnancy and by the weight of his authority the assumption was given validity, repeated in textbooks, but as far as can be found out, never very seriously investigated. De Lee ¹ elaborates the idea by stating that during pregnancy, from the first few months, there is a decrease of the red blood cells and an increase of the white blood cells, the latter out of proportion to the former yet seldom exceeding 15,000, that the younger forms increase so that the blood of pregnancy resembles that in an acute infectious disease, and further that the changes are more marked in primiparae. Williams ² mentions a leukocytosis during labor. Cragin ³ gives some average counts during pregnancy 10,600, during labor 12,800, the third and tenth days post partum 11,700 and 10,300. Polak ⁴ says that extreme changes are not seen, but that the number of white cells is increased and especially so in the later weeks of pregnancy. Jellett and Madill ⁵ repeat what appears in other texts, namely, that there is an increase in the white blood count toward the end of pregnancy. Bland ⁶ is a little more specific in that he sets an upper limit at 20,000, and declares that there is invariably an increase. Both of these latter authorities mention that the increase is largely polymorphonuclear and more likely to be marked in primiparae. Piney and Wyard ⁷ and Piney ⁸ specify a neutrophilic shift to the left, usually without any evidence of infection, and particularly definite in the later months. They assume it to be a physiologic condition. Inasmuch as there have seldom been actual figures given to substantiate these often repeated statements, we determined to establish, if possible, a basis for proof or disproof.

We have gathered together 977 white blood counts from 134 presumably normal pregnancies, 169 pregnancies were studied, but only those cases in which five or more counts were obtained were finally tabulated. Practically all of these women had, either during the period of prenatal observation, post partum, or at some other time contiguous to the pregnancy, a physical examination. They were all considered to be normal women. There were no abnormal conditions during the prenatal period of observation that we thought could in any way affect the leukocytic level. The only infections found were upper respiratory infections in four, Trichomonal vaginitis in four, acute enteritis in one, cervicitis in three, pyelitis in three. Only in the latter might there have been some effect on the white blood

woman was observed through two pregnancies, are tabulated (table 3). In a few isolated cases we found in the record white blood counts done when the patient was not pregnant. In some these differed, in others the pregnancy count corresponded very well with the interval count (tables 2 and 3).

All of these counts were done by one technician (H. B.), and most of

CHART 1

them were taken in the afternoon, usually later than two hours after the noon meal. A few counts were taken in the morning, usually about three or four hours after a meal. No attempt was made to control any factor which might affect the count, such as exercise, anemia, etc. All of the patients were ambulatory office patients.

We have chosen to chart the median curve, since the counts are not evenly distributed throughout the whole period of gestation, nor for any given month, and such a curve more clearly indicates the center value. The median is the middle case, so that 50 per cent of all counts are above and 50 per cent below. We have also charted the percentile lines, establishing the four quartile zones of variation. Lacking values of normal for non-pregnant women, we have assumed 10,000 to be the probable upper limit of normal, since counts higher than this are commonly considered pathological by most clinicians (chart 1).

There were in general three types of curves seen in a study of individual cases: one a curve that approximated the median one charted (table 2, cases 1, 5, and 6), another which remained throughout on a high level (table 2, cases 2, 4, and 8), and a third which remained throughout on a level well within normal limits (table 2, cases 3 and 7). It is apparent from the charted curves of median and percentile values, and also in the individual cases cited, that there is no consistent rise in the ninth month, also that less than 50 per cent of the counts are below 10,000. The impression is that some women respond with a leukocytosis to pregnancy and others do not.

There was nothing unusual in the cell morphology of those cases showing an elevation of the white count. The elevation seemed to be predominantly of the neutrophilic cells.

SUMMARY

1. Nine hundred and seventy-seven leukocyte counts in 134 normal pregnancies were obtained.

2. A count between 10,000 and 11,000 seems to be a median value for pregnancy, irrespective of time in pregnancy.

3. Fifty per cent of the counts were between approximately 8,700 and 12,500 throughout the nine months of pregnancy.

4. Less than 50 per cent of the counts were below a high normal of 10,000.

5. Seventy-five per cent of the counts were above 8,700.

6. Twenty-five per cent of the counts were above 12,500 or below 8,700.

7. There was no rise in the ninth month, except in a few individual cases which were not numerous enough to lift the curve.

8. Some patients remained consistently high throughout the nine months, others remained consistently low or normal.

9. There did not seem to be any significant difference between curves of counts in primiparae and multiparae.

10 There may be a physiologic leukocytosis of pregnancy, but it certainly is not invariable

We are indebted to Dr Edith Boyd for her help in preparing chart 1

THE CONTINUOUS METHOD OF TREATMENT OF EARLY SYPHILIS ¹

By JOSEPH EARLE MOORE, M D , *Baltimore, Maryland*

If early syphilis is properly treated, late syphilis will almost, even if not quite, disappear. That early syphilis is not being properly treated is obvious from the fact that late syphilis is not disappearing. On the contrary, in every urban American community syphilis heads the list of reportable communicable diseases, and of the cases reported, more than half are late cases ¹

The proper treatment of early syphilis is of importance from three standpoints: that of the individual patient, that of the public health, and that of the public expense. The individual patient requires proper treatment in order to accomplish "cure" and to prevent the development of usually serious, often crippling and disabling, and sometimes fatal late lesions. To utilize the two most serious of these, cardiovascular and neurosyphilis, as an

FIG 1

* Presented at the Detroit meeting of the American College of Physicians, March 3, 1936
From the Syphilis Division of the Medical Clinic, the Johns Hopkins Hospital

illustration figure 1 shows the approximate incidence of each in patients untreated or badly treated as compared with those given adequate early treatment. Similar data are available for all the late sequelae of the infection.²

From the standpoint of the public health, the spread of syphilitic infection may best be controlled by the elimination of the infectious patient

FIG 2

Figure 2 * shows that (1) an arsphenamine is necessary to prevent infectious relapse—heavy metal alone does not suffice, (2) less than four injections of an arsphenamine permits relapse in the astonishingly high total of 45 per cent, an incidence probably even higher than would occur if no treatment were given (though data on this form of relapse in untreated syphilis are lacking), (3) at least 20 injections of an arsphenamine are the absolute

* All figures except figures 1 and 10 are based on the data of the Cooperative Clinical Group (the Syphilis Clinics of the Universities of Pennsylvania, Michigan, Western Reserve, Johns Hopkins University, and the Mayo Clinic). The papers on which these charts are based are listed in the bibliography as reference 3.

Figures 2, 7, 8, and 9 have been prepared by the American Social Hygiene Association and are here published for the first time with permission. These and 19 other similar figures illustrating the studies of the Cooperative Clinical Group on early and latent syphilis are available in pamphlet form (price 30 cents) from the American Social Hygiene Association, 50 West 50th Street, New York.

minimum required nearly to eliminate infectious relapse. The practical abolition of infectious relapse is related not only to the total amount of treatment given, but also, as will be shown, to its type. It is important here to emphasize, however, that the public health aim of treatment, and the end sought in the individual patient, require a type and total amount of treatment not very different for the one than for the other.

The economic aspect of the proper treatment of early syphilis is of fundamental importance. Hospital beds, both general and psychiatric, are filled with patients who must be treated and maintained at public expense, who are no longer a menace to the public health since they are no longer infectious, and whose prospect of "cure" or even of symptomatic relief is, as compared with early syphilis, negligible. In Baltimore, the annual expense of hospital care for such patients, for the average year (determined in 1933) is \$100,000.⁴ If this sum is expended in one city of not quite a million people, it is a fair estimate that the hospitalization of broken down late syphilitics (whose illness is nearly irremediable) in the country at large costs approximately \$12,400,000 annually. The amount of money expended by Health Departments and privately endowed hospitals on the ambulatory care of patients with early syphilis, i.e., at a time when "cure" can be accomplished and the development of late sequelae requiring hospitalization prevented, cannot be so readily estimated but is probably nowhere nearly so large a sum. It seems logical to conclude that the expenditure of money is being made in the wrong place, and that by increasing greatly the amount spent on the proper care of early syphilis, the ultimate cost of late syphilis could be greatly reduced.

If one grants that, by and large, early syphilis is not being properly treated, it is wise to enquire into the reasons for this difficulty. The fault seems to lie in part with the biology of syphilitic infection, in part with the laity, and in part with physicians.

It is now quite clear that in some patients, perhaps in many, who are infected with syphilis, the lesions of primary and secondary syphilis are either wholly absent or so trivial and transitory as not to attract the attention of even the most observant individual. Infection has been, for all practical purposes, symptomless. If a patient does not recognize symptoms serious enough to take him to the physician at all, obviously he cannot be treated. Such patients form an as yet unmeasured reservoir for the spread of infection to others, and for the ultimate development of late syphilis. The physician has only one defense against this biologic silence of syphilitic infection, namely the use of the routine serologic test for syphilis on every possible occasion. Case finding is as important in syphilis as it is in tuberculosis.

The fault which lies with the laity is ignorance, and worse still, unwillingness to learn. Many individuals, perhaps most, know little or nothing of syphilis—its symptoms, its late complications, its prevalence. Most persons know only that the disease is "venereal" and usually contracted through sexual intercourse. The sex taboo forms the barrier to the acqui-

sition of accurate knowledge. There is a "conspiracy of silence" concerning syphilis. The press, daily and periodical, and the radio, too often bar even the mere mention of the word, let alone informative discussion concerning it. The public must be educated to know what syphilis is, and trained to consult a physician for its earliest symptoms as it has been similarly trained for tuberculosis and cancer. The dangers of quack, drug store, or self treatment must be pointed out. Until the patient knows enough about his possible illness to consult a physician for it, the hope of getting him under early treatment is an idle one. Until he knows something of the requirements of proper treatment, and the possible consequences of evading it, it is useless to expect his cooperation in carrying it out.

The fault of the medical profession is threefold: that it has not taken the lead in education of the laity, that it does not apply modern methods to early diagnosis, and that, though adequate treatment methods have been developed, it does not apply them. Further discussion of the educational aspects of the problem are beyond the scope of this paper. It is essential to point out, however, that the reasons for the failure to control the syphilis problem are not wholly due to the inadequacy of current modern treatment.

To concentrate now on the question of treatment, it is readily apparent that the failure of physicians as a group is due in small part to technical ineptitude, and in large part to the persistence of empiricism. There are a few simple principles applicable to the treatment of early syphilis, all of which are backed by sound experimental and clinical evidence. These are

- (1) Successful treatment depends on early diagnosis
- (2) The choice of drugs is limited to the arsenicals represented in the arsphenamine group, and to bismuth
- (3) Treatment should be continuous from start to finish, i.e., without rest periods of any sort
- (4) Treatment must be prolonged to a minimum of (depending on the stage of infection) 12 to 18 months
- (5) Determination of "cure" requires life long post-treatment observation

The importance of early diagnosis is shown in figure 3. The patients on whom this chart is based were treated by several different methods and in varying amounts—not with the best method and for the optimum time. Even with this handicap seronegative primary syphilis is 72 per cent "curable", whereas the prospect of "cure" drops by 20 per cent with the few days' or weeks' delay necessary for the development of a positive serologic test or secondary lesions. To increase the probability of early diagnosis of seronegative primary syphilis, it is essential (1) to educate the layman to consult a competent physician at once on the appearance of any genital sore, (2) to educate the physician to use the dark field microscope or to refer his patient to some one who can.

The choice of drugs is limited to the arsenicals represented in the arsphen-

amine series, and to bismuth. This point should not require elaboration. No other arsenical drug is known which is of comparable value to the arsphenamines in early syphilis, though one still sees patients treated with

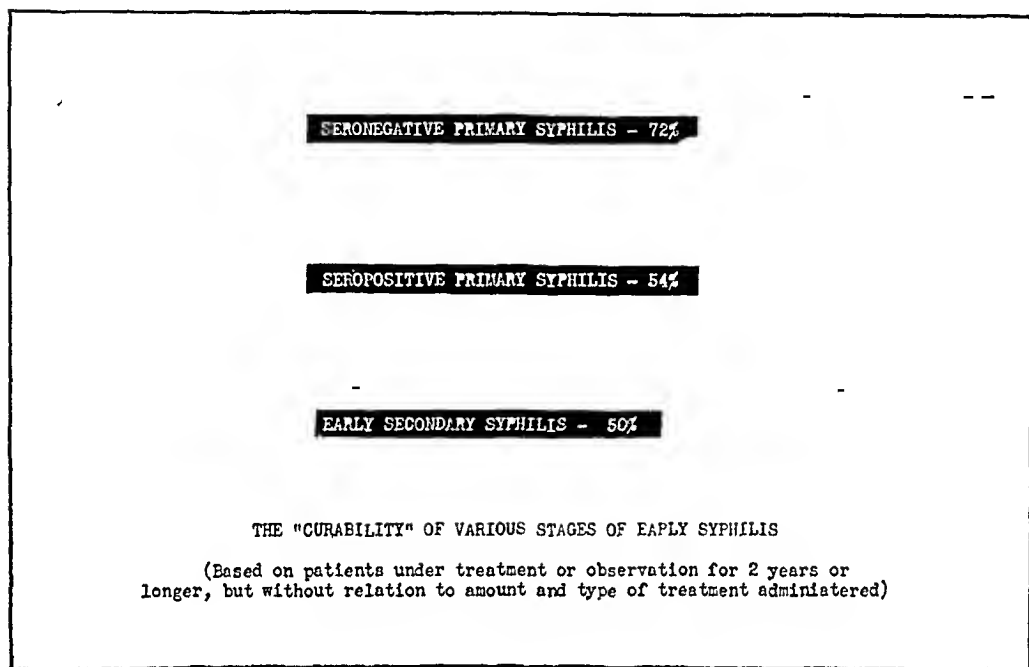

FIG 3

pentavalent arsenicals (useful only in neurosyphilis), with sodium cacodylate, or with bizarre and untried arsenicals boosted by pharmaceutical houses. Among the arsphenamines, only arsphenamine itself (606), neoarsphenamine (914), silver arsphenamine, and mapharsen (arsenoxide) are worthy of serious mention, and in spite of the 25 years of study devoted to the subject, a serious comparison as to the relative merits of these four is available only for arsphenamine and neoarsphenamine (mapharsen has been too recently introduced for comparative data to be evaluated). As between 606 and 914, however, the advantage is definitely with arsphenamine. Figure 4 shows that the prospects of "cure" are 16 per cent greater, and the prospects of clinical relapse 5 per cent less with arsphenamine than with neoarsphenamine. This variation seems to be too slight to persuade the average physician to use the technically difficult arsphenamine in place of the technically easy neoarsphenamine. Fortunately, however, it is probably true that arsphenamine results can be approximated with neoarsphenamine if larger doses and longer courses of the latter are given to compensate for its therapeutic inferiority. As a matter of fact, it is probable that satisfactory results may be obtained with any of the four arsphenamines mentioned, if they are given in adequate dosage by the continuous system and for a long enough time.

As between bismuth and mercury, the advantage is definitely with bismuth, as is shown in figure 5. Where arsphenamine plus bismuth is given serologic reversal is 12 per cent more frequent, and infectious relapse 6 per

FIG 4

cent less frequent, than if the same amount of arsphenamine plus mercury is used. The bismuth preparation employed should not be, for reasons beyond the scope of this paper, water soluble, but should be liposoluble or an insoluble salt suspended in oil.

Treatment should be continuous. The reasoning which led to the adoption of this method of treatment is briefly as follows, and is based on the interplay of the biology of syphilitic infection, the mechanism of drug action, and the phenomenon of drug resistance.

Early syphilis may occasionally be "cured" by one or a few injections of an arsphenamine, with or without associated heavy metal. In the majority of patients, however, biologic "cure" does not result from a small amount of treatment. Treatment, whether adequate or inadequate, interrupts the development of resistance (or immunity) to the virus, and may actually depress it, by preventing the normal sequence of events in an un-

treated patient, i.e., gradually developing insusceptibility to reinfection, spontaneous healing of secondary lesions, spontaneous destruction of treponemes, and latency. If treatment is inadequate (or intermittent), and the patient is left, at the beginning of the first rest period, with living treponemes in his tissues, he must elaborate his immune reactions afresh against these remaining organisms. Depending on the location of the surviving organ-

FIG 5

isms and the interval between treatment courses, he may not develop obvious clinical or serologic evidence of relapse, though some degree of biologic relapse may be expected unless the amount of treatment before the rest period has been adequate to destroy every treponeme.

If treatment is purposely intermittent, combining an arspenamine and a heavy metal in a single course, rest periods are obligatory because (1) the patient's tolerance to toxic drugs must not be exceeded, (2) experimental and clinical evidence indicates that sometimes, if not always, the organisms acquire a tolerance for the drugs employed, and become drug resistant. Under these circumstances, the obligatory rest period, leaving the patient

without the protection either of chemotherapeutic treatment or of his own defense mechanism, paves the way for relapse

With continuous treatment, on the contrary, courses of an arsphenamine may be given in alternation with courses of a heavy metal, without rest periods of any sort. Under these circumstances, the patient's tolerance for

FIG 6

toxic drugs need not be exceeded, the phenomenon of drug resistant strains of organisms need not be feared (since drug resistance is usually drug specific), and most important of all, the patient's own defense mechanism is constantly augmented or replaced by the continuous effect of treponemicidal, treponemistatic, or resistance-building drugs

The test of this reasoning is, of course, the results obtainable in human beings by the use of the method. Moore and Kemp,⁶ in 1926, presented data showing the superior results of continuous over intermittent treatment, and their findings have been confirmed on a much larger scale by the Co-operative Clinical Group and by the League of Nations enquiry into syphilitic treatment. From all points of view studied, both major and minor, the treatment of early syphilis is more successful with the continuous than with any other method. Here it is necessary only to discuss briefly three of the most important points: (1) the ultimate clinical outcome, i.e., the probability of "cure", (2) the incidence of clinical relapse, and (3) serologic reversal.

The Cooperative Clinical Group studied the results of four methods of treatment, diagrammed and explained in figure 6. The continuous method accounts for 14 per cent more "cures" in all types of early syphilis and for

FIG 7

8 per cent less relapses, than its nearest competitor, intermittent treatment. Interestingly enough, the intensive (Pollitzer) system gave the poorest results of all, even worse than those of the most haphazard and irregular

FIG 8

treatment (figure 7), a point of considerable interest in view of the revival of a modification of this idea by Chargin and his associates

The difference between the various treatment schemes in bringing about serologic reversal within a given period of time is even more striking. In figure 8 it is shown that serologic negativity was achieved within a year in 82 per cent of those treated continuously, in less than half as many when treatment was intermittent, and in only 5 per cent of those treated irregularly. The converse of this chart is the obvious fact that in early syphilis, a faulty treatment method may actually be responsible for that feature of

FIG 9

syphilotherapy which most disturbs the average physician, namely, Wassermann fastness

More serious still, intermittent or irregular treatment causes an increased incidence of serologic evidence of invasion of the nervous system, i.e., asymptomatic neurosyphilis. Fortunately for the patient, though not generally appreciated by the therapist, there is a close relationship between the incidence of these two factors, asymptomatic neurosyphilis and Wassermann fastness (figure 9). If in early syphilis (not true of late syphilis) the blood serologic test remains persistently positive for six months or longer, the

cerebrospinal fluid is nearly three times as likely to show evidence of neuraxis invasion as when serologic reversal has occurred. A persistently positive blood test in treated early syphilis urgently demands routine spinal fluid study. If asymptomatic neurosyphilis is present, intensification or modification of the routine treatment scheme is required.

Treatment must be prolonged to a minimum (depending on the stage of infection) of 12 to 18 months. While it is true that some patients are "cured" with much less treatment than this, there is no way in which such fortunate individuals may be recognized before or during treatment. It is essential, therefore, to give all patients enough treatment to "cure" the most resistant member of the group, even though this amount is more than some may need. The minimum duration of treatment has been arrived at on the basis of prolonged experience under rigid serologic and clinical control. The essential data justifying the standard named are presented in figure 10, which shows the approximate probability of "cure" with varying

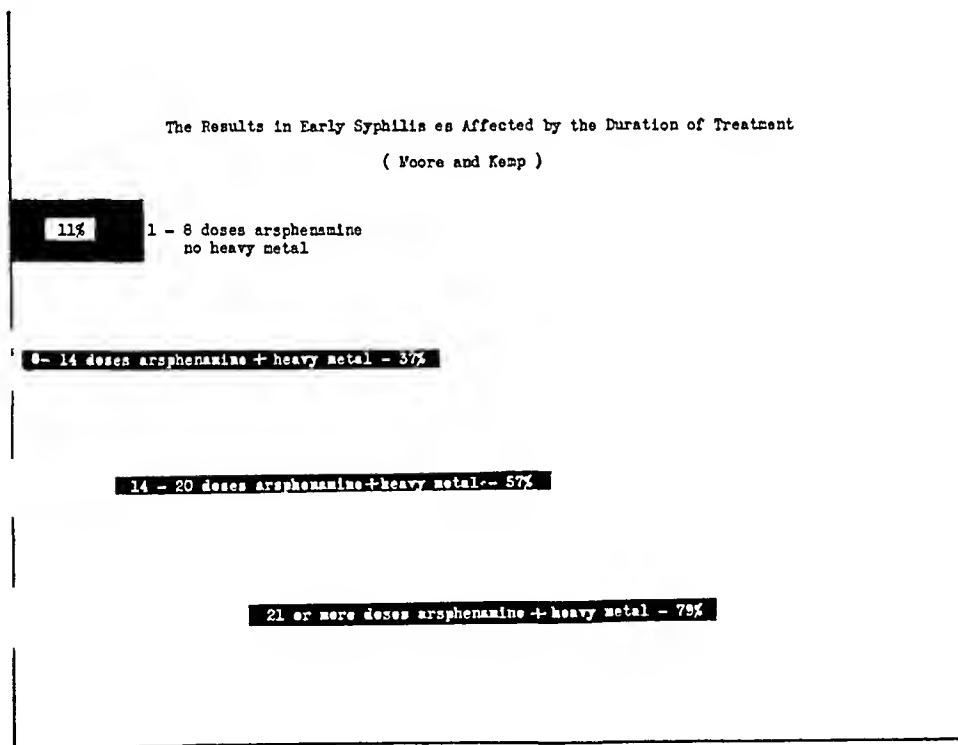

FIG 10

amounts of treatment. It must be remembered that these data are applicable only to patients with uncomplicated early syphilis, in whom the course of the disease and of treatment has been uneventful. Patients with clinical or serologic relapse, with treatment resistance, with grave treatment reactions which interfere with subsequent intensive treatment, and with asymptomatic neurosyphilis, are not included. For such persons, treatment is a

highly individualized procedure, usually demanding expert consultative advice

The optimum duration of treatment is slightly shorter if the diagnosis is made and treatment started during the seronegative primary stage, when, given a cooperative patient and no complications, "cure" is nearly certain with 12 months of continuous treatment. With seropositive primary and early secondary syphilis, 18 months of treatment are required to produce results which are not quite so certain.

The duration of treatment may be measured if desired, though preferably only by the expert, by serologic standards. On this basis, the criterion set by Keidel 20 years ago still holds good, namely, one full year of continuous treatment after serologic tests of blood and cerebrospinal fluid have become and have remained completely negative. Since the use of such a standard demands frequent repetition of serologic tests, thereby adding to the cost of treatment, and since difficulties of interpretation of such serial serologic testing confront both the inexperienced physician and his anxious patient, it is probably better for the average practitioner to discard the serologic method of treatment control and to rely on the arbitrary standard already mentioned. These standards, i.e., 12 months of continuous treatment for seronegative primary syphilis and 18 months of continuous treatment for seropositive primary or early secondary syphilis, are in fact based upon the correlation of clinical and serologic standards in thousands of patients treated under expert control.

Determination of "cure" requires lifelong post-treatment observation. There is no other criterion of "cure" in human beings. Until quite recent years it was the custom even for the expert to dismiss his well treated patient as "cured" within 1 to 3 years after the completion of treatment, and this brief observation period is still the custom of the less experienced physician. Brief thought as to the extreme chronicity of syphilis in untreated, or if treated in uncured, patients shows the advisability of prolonged follow-up. Fifteen to 20 years after infection usually elapse before the development of obvious signs of the two important late sequelae, cardiovascular and neurosyphilis. To protect one's treated patient against such disasters, a year or two of casual post-treatment observation is not enough, the patient must be followed for a life time. The treated syphilitic patient is the ideal subject for the periodic health examination.

SUMMARY

Though the adequate treatment of early syphilis is of importance from the standpoints of the individual patient, of the public health, and of the public expense, and though proved adequate treatment methods are available, they are not being generally applied.

The reason for this failure lies in part in the biology of syphilitic infection, i.e., in the fact that it is sometimes, perhaps often, symptomless in

the early stages, in part in lack of knowledge of the laity of the prevalence, characteristics, and public and individual importance of syphilitic infection, in part in the failure of the medical profession to employ adequate methods of early diagnosis and treatment. Remedies for these three faults are briefly suggested.

The modern treatment of early syphilis is based on five fundamental principles, as follows

- (1) Early diagnosis
- (2) The use of drugs of proved worth
- (3) The use of a continuous treatment system, without rest periods
- (4) The use of treatment prolonged to an arbitrary minimum of 12 to 18 months
- (5) Determination of "cure" by lifelong post-treatment observation

GLANDERS¹

By RALPH W. MUNDLSON, M.D., F.A.C.S., F.A.C.P.,
Albuquerque, New Mexico

GLANDERS, although an uncommon disease in man, is so frequently misdiagnosed, so pernicious in its manifestations and of such great importance as a public health problem when it does occur that it merits more attention than it has so far received. There are but few states that provide, in their public health laws, for the protection of their residents against this disease. Since the advent of the motor car, glanders in man has materially decreased, but in rural districts and especially in the southwestern states many cases probably go undiagnosed and constitute a genuine danger to the public health.

Strictly speaking the term glanders should be limited to the infection of the nasal mucous membrane and the internal organs, while the term farcy designates the skin and lymphatic manifestations of the same disease. In general terms glanders may be defined as a specific infectious disease due to the *Bacillus mallei*,[†] not uncommon in the horse, mule and ass and contracted by man through immediate contact with an infected animal.

Glanders may be either acute or chronic. The acute type is very frequently devastating in the rapidity of its evolution and often takes the form of a septic pneumonia secondary to a primary nasal mucous membrane infection. It is often mistaken for general sepsis, the nature of the primary lesion passing unrecognized. The acute cases are usually fatal and from a public health point of view not as important as the chronic type.

Chronic glanders presents no characteristic symptomatology. The essential lesion is an infectious granuloma that breaks down, as a rule, rather rapidly with the formation of slow healing ulcers in the skin and mucous membranes and deep seated abscesses in internal organs, muscles and other parts of the body. Bone infections have been noted. In cases where the virulence of the infecting organism is low, there is considerable epithelioid cell formation and also giant cell production. This type of lesion is not unlike a tubercle. These patients present symptoms of a chronic septic character with intervals of remission that may be short or long. A very few recover, the majority succumb to an acute exacerbation usually with acute pulmonary manifestations.

The two cases I have to report are of the chronic insidious type with no initial acute manifestations. The first case was under observation but a short time, while the second one has been observed for over five years.

* Received for publication June 1, 1935.

CASE REPORTS

Case 1 A white female, aged 36 Her previous history is irrelevant except that she was reared on a farm and that she came into intimate contact with two horses that died of an unknown disease 18 months previous to her present examination Shortly after the death of the above mentioned horses she first noticed a slight nasal discharge followed shortly by the formation of an ulcerated patch on the tip of the nose The nasal discharge gradually increased and became mucopurulent, while the skin lesions advanced until the entire upper lip and nose presented an ulcerated, discharging mass She consulted a number of physicians and the diagnosis varied from syphilis and tuberculosis to epithelioma At no time did she suffer from marked constitutional symptoms At the time of examination the patient was well nourished and the physical examination revealed no abnormalities except as portrayed in figure 1

FIG 1 The glanders lesions of the nose and lip in case 1

The temperature, blood count and urine examination were all normal The blood Wassermann was negative Tests for the tubercle bacillus were negative and tissue examination revealed no malignancy (Figure 2) There were no laryngeal symptoms The skin lesions were covered with a thick, yellowish crust which after removal revealed many small ulcerations on a surface of granulating tissue Smears from the discharge from the nose and from the skin ulcerations revealed a mixed infection with many gram-negative, slightly curved rods This organism proved to be *Bacillus mallei*, and the patient's blood agglutinated a known organism in dilutions up to 1-160 Treatment with an autogenous vaccine, together with such local treatment as was indicated, was instituted, but the patient refused to remain under my care and the eventual outcome in this case is not known

Case 2 A Mexican youth, aged 15, presented himself for treatment because of the loss of sight in one eye, a severe infection in the other eye, a mucopurulent discharge from the nose and extensive ulceration of the nose and upper lip as shown in figure 3

His previous history was irrelevant except that he had come into intimate contact with a horse that had died from some unknown disease shortly before he became ill. The patient stated that the disease manifested itself first by a redness and discharge from the lower lid of the left eye. One and one-half years later this was followed by a discharge from the nose and ulcerations of the tip of the nose that gradually spread to the upper lip. He next noticed some slight hoarseness and difficulty in swallowing. About six months previous to his present examination (July 1929), his right eye became infected. At no time did he suffer any constitutional

FIG 2 Section from case 1, showing granulomas made up of masses of epithelioid cells with central necrosis. There is abundant leukocytic infiltration. No giant cells are to be seen in this section.

symptoms. On physical examination he presented an emaciated body, considerable enlargement of all of the glands in the neck, a normal blood count, a negative Wassermann and a normal urine examination. The right eye showed considerable corneal ulceration with a high degree of conjunctival inflammation. The left eye presented old corneal ulcers, moderate conjunctival inflammation and considerable mucopurulent discharge. There were no ulcers in the oral cavity, the membranes were injected and there was a well marked nasopharyngeal discharge. The external nasal passages were blocked with encrusted, yellowish deposit (Figure 3). The skin lesions were covered with a thick, encrusted mass of discharge that involved the

FIG 3 Case 2, before treatment

FIG 4 Case 2, six months after treatment with autogenous vaccine

mucous membrane of the upper lip to the gum line. Removal of the crusts revealed an ulcerating, granulomatous tissue from which was obtained a mixed infection with many gram-negative, slightly curved rods that proved to be *Bacillus mallei*. This patient's blood agglutinated a known culture in a dilution of 1-160. Treatment of this case consisted of various local treatments and autogenous vaccine. The condition of

FIG 5 Case 2, three years after vaccine treatment

the patient six months after treatment is well defined in the illustration (figure 4). After this period of treatment the patient left my service and I did not see him for a period of about two years when he returned and his condition at that time is well portrayed (figure 5). He also has developed in the meantime a large ulceration on the left elbow from which *B. mallei* can be recovered.

COMMENT

The diagnosis in these cases is of course suggested by the history, the characteristic nasal discharge and the ulcerations. Differential diagnosis must take into consideration epithelioma, syphilis and tuberculosis. In the tropics one must also consider the possibilities of a framboesial infection.

These diseases are not difficult to eliminate. Agglutination tests are of primary importance in confirming the diagnosis, and one may either agglutinate the patient's serum against a known organism or, having isolated the specific organism from the patient's lesions, agglutinate it against a known serum.

Regarding the treatment one must not be too optimistic. Apparent cure is often followed by relapse and not infrequently a case will subside without the benefit of medication. Watson of Canada reports good results with the use of hyperimmune serum, but this is difficult to obtain. Autogenous vaccine with indicated local treatment has been my choice, and in view of the tendency to relapse in spite of apparent cure it is advisable to keep these patients under observation for many years. They are at all times a danger to the public health during the active stages of the disease and should be under strict quarantine. While enjoying periods of inactivity they should report at frequent intervals for observation.

THE LOCALIZATION OF SUPRATENTORIAL TUMORS OF THE BRAIN BY OLFACTORY TESTS

By CHARLES A. ELSBERG, M.D., *New York, N. Y.*

IN a series of papers published in the Bulletin of the Neurological Institute of New York (1935, 1936) new quantitative procedures for the examination of the olfactory sense were described. One of the procedures was called *blast injection of odors* and consists of the injection of measured volumes of odor into one or both nasal passages during short periods of voluntary cessation of breathing. In this procedure the pressure under which the blast of odor is released into the nose takes the place of the force of the ordinary inspiratory movement.

The smallest number of cubic centimeters of an odor that can normally be identified by the blast injection test was called the MIO (minimum identifiable odor) of the odorous substance. The MIO of any one substance was found to have about the same value in all normal individuals.

A second method was called *stream injection of odors*. In this procedure a continuous stream of odor is injected into one or both nasal passages for a period during which the individual who is being examined breathes through the mouth. The stream injection of odors was used to produce olfactory fatigue and to study the trigeminal effects of odors. Here again it was found that the duration of olfactory fatigue for any odor produced by stimulation of the olfactory receptors was about the same in all normal individuals. The effects of blast injection and stream injection of a variety of odors were investigated in a large series of healthy individuals, and information was gained regarding the nature of the olfactory stimulus, the relative importance of pressure and volume of the olfactory stimulus for the olfactory impulse, the physiological aspects of monorhinal, binorhinal and bisynchronorhinal smell, and the nature of and organic basis for olfactory fatigue.

Finally two odorous substances—coffee and citral—were selected for clinical tests of the sense of smell. These two substances were chosen because their odors are familiar, and because the odor of one of them—coffee—is a pure olfactory stimulant, while that of citral affects both the olfactory and the trigeminal nerves. Several years were spent in the study of the sense of smell in normal individuals. Finally, in order to learn whether the methods were of value for the localization of tumors of the brain, the tests were used in patients in whom an intracranial neoplasm was suspected.

Up to the present time, we have examined 118 patients in whom an intracranial growth was suspected or considered a possibility. In 52 of the cases,

* Read by invitation at the meeting of the American College of Physicians, Detroit, Michigan, March 2, 1936.

the situation of a neoplasm was verified by operation, autopsy or by pneumography. These 52 cases form the basis for this report.

In order that the reader can appreciate the results and the significance of the tests, it is necessary to give a short description of the procedures called *blast injection* and *stream injection of odors*. The apparatus and methods have been described in detail in other publications.

For our present purpose it will suffice to explain that after the M I O of each side of the nose had been determined, the duration of olfactory fatigue produced by the stream injection of the odors for 30 seconds at a volume-rate of 2000 c c to the minute was established for each side of the nose.

The presence of gross abnormalities in the nasal passages was first excluded by the Zwaardemaker test. Then blast injections of the odor of coffee were given into one nasal passage at intervals of 30 seconds until the smallest volume of odor that could be identified at three successive blast injections was determined. After the value of M I O of one side had been found and the patient had been given a few minutes of rest, the M I O of the other side was determined by blast injections. Then, again after a few minutes of rest, the patient was given a stream injection of coffee odor into the nasal passage that had been tested first. The duration of the ensuing olfactory fatigue was established by giving, every 30 seconds, blast injections of the volume that had been necessary for M I O, until the ability to identify the odor as coffee had returned. After another rest period, the procedure was repeated on the other side of the nose. Later, similar blast injection and stream injection tests were made with citral. By these procedures the M I O and the duration of olfactory fatigue on each side for coffee and for citral were established.

TABLE I
The Determination of M I O for Coffee in Case 1
Blast injections of coffee odor given every 30 seconds into

Right Side (c c)	Left Side (c c)

15 - 0	6 - 0
15 - 0	6 - 0
16 - 0	7 - +
17 - +	7 - + = M I O
17 - +	
17 - +	
16 - 0	
16 - 0	
17 - + = M I O	

* + = odor identified, 0 = odor not identified

The number of blast injections required in a patient before the M I O for coffee of each nasal passage had been obtained is shown in table 1. The table illustrates the steps of the procedure by which M I O is established.

Table 1 shows that on the right side 17 c c were the smallest number of c c that were identified on three successive blast injections into the right nasal passage, and 17 was therefore the M I O on the right side. Similarly 7 was the M I O on the left side.

Sometimes, as in the instance above given, the M I O can be established by a relatively small number of blast injection tests, at other times a larger number of blast injections has to be given before the examiner is certain that he has obtained the correct values for the M I O. Because the injections of volumes of odor corresponding to M I O are used in order to determine the duration of olfactory fatigue, it is important that in the preliminary blast injection tests the volume necessary for M I O be accurately determined.

THE CHARACTER OF THE CHANGES FOUND BY THE OLFACTORY TESTS AND THEIR SIGNIFICANCE FOR LOCALIZATION OF THE GROWTH

In order that the significance of the figures obtained in patients with tumors of the brain may be appreciated, a table of the results of tests in a few healthy individuals is given (table 2). In this table the duration of fatigue is the number of minutes which elapsed after a stream injection of the odor for 30 seconds at a volume-rate of 2000 c c per minute, before the odor was again identified.

TABLE II
The Normal M I O and the Duration of Fatigue in 6 Normal Individuals

Name	Coffee				Citral			
	M I O		Duration of Fatigue		M I O		Duration of Fatigue	
	Right	Left	Right (min)	Left (min)	Right	Left	Right (min)	Left (min)
V O	9	9	2	2	8	8	2.5	3
J B D	8	8			7	7	2.5	2.5
C C H	8	8	2	2	7	7	2.5	2.5

Result of Olfactory Tests

Low M I O indicates increased intracranial pressure

Duration of fatigue normal on left, prolonged on right

Conclusion Right hemisphere tumor—not deep

These records illustrate some of the results of olfactory tests made in patients with verified tumors of the brain. The analysis of the results in the 52 cases which form the basis for this paper has permitted us to draw the following conclusions:

1 *In subfrontal extracerebral growths, the M I O on one or both sides is elevated, while the duration of olfactory fatigue is not prolonged.* If the neoplasm is small and is entirely unilateral, the elevation of M I O is found only on the same side, if the growth is large, the M I O may be raised on both sides and the greater elevation of M I O is found on the side on which the growth or the larger part of the growth is situated. Thus in small aneurysms of the internal carotid artery and mesial sphenoid ridge meningiomas, the M I O is elevated on the affected side and normal on the other side. In the case of a larger aneurysm or tumor, the M I O is elevated bilaterally. Meningiomas attached to the dura of the cubiform plate of the ethmoid or of the tuberculum sellae produce a bilateral elevation of M I O. In pituitary tumors that have not extended through the diaphragm of the sella, the M I O is normal, but as soon as the growth has become suprasellar, pressure is exerted upon the extracerebral olfactory pathways and the M I O is elevated unilaterally or bilaterally.

Case 6 Deep left hemisphere glioma

Clinical Symptoms For 8 months vague disturbances of left upper extremity Examination shows hyperactive tendon reflexes on left papilledema of 4 diopters, bitemporal hemianopsia

Ventriculography Lateral and third ventricles displaced to right

Olfactory Tests

Result of Olfactory Tests

M I O low for coffee and for citral

Duration of fatigue prolonged on left

Conclusion Increased intracranial pressure

A deep intracerebral tumor in the left cerebral hemisphere

2 In supratentorial tumors within the substance of one cerebral hemisphere the M I O may be normal or smaller than normal, but the duration of homolateral fatigue is definitely prolonged Apparently the degree to which the duration of olfactory fatigue is prolonged depends upon the extent to which the neoplasm involves deeper parts of the brain The more deeply a tumor is situated, the longer is the duration of the fatigue produced by the procedure If the fatigue lasts more than ten minutes, the growth extends to near the midline or actually lies in the midline

3 In tumors in the substance of one frontal lobe, the M I O is elevated and olfactory fatigue is prolonged on that side The elevation of M I O is due to pressure upon the extracerebral olfactory pathways of the same side as the growth Therefore the combination of elevation of M I O and prolonged duration of fatigue must mean that the neoplasm is in the corresponding frontal lobe

4 In patients with increased intracranial pressure due to tumors of the brain, there is frequently an increased irritability of the olfactory pathways,

Case 7 Glioblastoma multiforme in left frontal lobe extending across midline into right frontal lobe

Clinical Symptoms Four weeks' history of right hemiparesis and papilledema

Result of Olfactory Tests

M I O elevated on both sides, left more than right

Fatigue prolonged on both sides for coffee and on left for citral

Conclusions A deeply situated tumor in the left frontal lobe near the midline The growth has probably extended also into the right frontal lobe

which is shown by values of M I O smaller than the normal While low M I O is often seen in patients with increased intracranial pressure, it does not follow that low M I O always means increased tension within the cranial chamber Low M I O's were frequently observed in diseases of the brain in which there was no increase of intracranial pressure On the other hand, in patients with papilledema and other evidences of increased pressure, the M I O may be within normal limits

The study of the sense of smell by the blast injection and the stream injection of odors is therefore of value for the localization of supratentorial tumors of the brain In some instances the olfactory tests did not show any evidence of a localized lesion and in these instances it was possible to conclude that the patient did not have a supratentorial neoplasm A more extended experience may show that the tests are of value for diagnosis as well as for localization, but up to the present time, the tests should be used

only for the localization of tumors of the brain. When employed for this purpose, the new olfactory tests may give information which may not be obtained by clinical examination. In unlocalized tumors of the brain, it is possible from olfactory tests to determine that a growth is in or under one or other frontal lobe, and if the growth is not frontal, whether it is in the right or left cerebral hemisphere. In the near future a procedure will be described by which tumors in or under one or other temporal lobe can be localized by olfactory tests.

ERRORS IN THE CLINICAL APPLICATION OF ELECTROCARDIOGRAPHY

By WILLIAM B BREED, M D , F A C P , and JAMES M FAULKNER, M D ,
F A C P , *Boston, Massachusetts*

THE last twenty years have seen an enormous growth in the use of the electrocardiograph as a diagnostic instrument. From a cumbersome and expensive machine available only to the larger hospitals and clinics have been developed models which are light enough and cheap enough to be entirely practicable for use in office or home. It is estimated that there are three thousand electrocardiographs in active use in this country today and the number of instruments is rapidly increasing. A result of this tremendous growth has been that we as internists are being called upon more and more to assess the clinical significance of electrocardiographic abnormalities.

When one examines the body of data on which much of our diagnostic and prognostic criteria in electrocardiography rest, one is struck by the paucity of suitable control material. Quite naturally most of the studies which have been made in this field were carried out on patients who came to a clinic because of suspected heart disease. The due prognosis which soon came to be associated with many electrocardiographic signs was therefore based in part on statistics from a selected group heavily weighted with bad risks. The very fact that an electrocardiogram was taken usually meant that the patient had either symptoms or signs suggestive of heart disease.

One example of overemphasis of the seriousness of an electrocardiographic finding has been in the case of bundle branch block. In the beginning we were inclined to assign a bad prognosis to every case exhibiting this sign, but as the years have gone by we have seen more and more patients with bundle branch block outliving their brief expectancy of life by many years. Although such signs of course merit serious consideration, our experience has made us more cautious about attaching prognostic significance to isolated electrocardiographic abnormalities.

From the point of view of negative evidence it has been recognized from its earliest application to clinical diagnosis that the electrocardiogram may be normal in the presence of obvious organic heart disease and consequently the importance of negative records has been duly discounted.

The subject of this paper deals with the occurrence of certain positive abnormalities—perhaps better termed peculiarities—of the electrocardiogram in the absence of organic heart disease. The importance of these peculiarities lies in the fact that they may simulate changes associated with serious cardiac disorders and thus may lead to grave diagnostic error. We

* Presented at the Detroit meeting of the American College of Physicians, March 3, 1936

do not include in this discussion the alterations in the electrocardiogram dependent on infections, toxemia or anoxemia

Abnormalities in the contour of the electrocardiogram result from abnormal relationships between the pathways of conduction and the recording electrodes. Therefore, in addition to intrinsic lesions of the conducting system and myocardium, unusual positions of the heart in the chest may be reflected in peculiar electrocardiographic patterns

RIGHT AXIS DEVIATION

FIG 1 Right axis deviation in a normal vertical heart

The effect of position of the heart on the electrical axis has been too well recognized to require more than passing comment. Figure 1 is a record of an individual with a normal heart in a vertical position. It shows right axis deviation.

Figure 2 shows left axis deviation resulting from a transverse position of the heart in a normal, healthy young man of sthenic habitus. Deep inspiration swings the electrical axis into the normal zone. Less well recognized is the fact that high diaphragm may cause the development of a deep Q-wave and an inverted T-wave in Lead III.

In rare cases the position of the heart may determine the direction of the

T-wave in Lead II The following case, presented through the courtesy of Dr Howard B Sprague, illustrates this condition

FIG 2 Left axis deviation in a normal transverse heart Note shift in axis to normal with depression of the diaphragm in inspiration

G C, a 19 year old boy, was referred to him in December 1935 because on routine examination as a college freshman he was found to have tachycardia and hypertension His past history was irrelevant He played football in high school He had no symptoms of any sort

Physical examination in general was negative The heart was not enlarged The action was rapid with marked sinus arrhythmia No murmurs were heard Blood pressure was 135 mm Hg systolic, 90 mm Hg diastolic Roentgen-ray examination showed the heart to be normal in size, shape and position

Figure 3 illustrates the marked effect of change in position of the heart on the T-waves particularly in Lead II On deep expiration the T-waves previously inverted became upright Because of its peculiar lability and in the absence of any other evidence of heart disease it was concluded that the inversion of the T-wave in Lead II did not signify myocardial disease and the boy was allowed to resume full activity

Another type of electrocardiographic peculiarity is caused by nervous influences upon intraventricular conduction The first case of this type was reported by Dr Frank N Wilson¹ of Ann Arbor in 1915 A group of them which correspond to a fairly distinctive pattern were described by Wolff, Parkinson and White² in 1930 and have come to be known by the term "functional bundle branch block" This condition is characterized by a very short P-R interval and prolonged intraventricular conduction with slurring of the initial phase of the ventricular complex The mechanism appears to be dependent upon a certain amount of vagal tone and may be abolished by atropine, adrenalin or exercise Clinically it is usually associated with a history of paroxysmal tachycardia but with no other cardiac

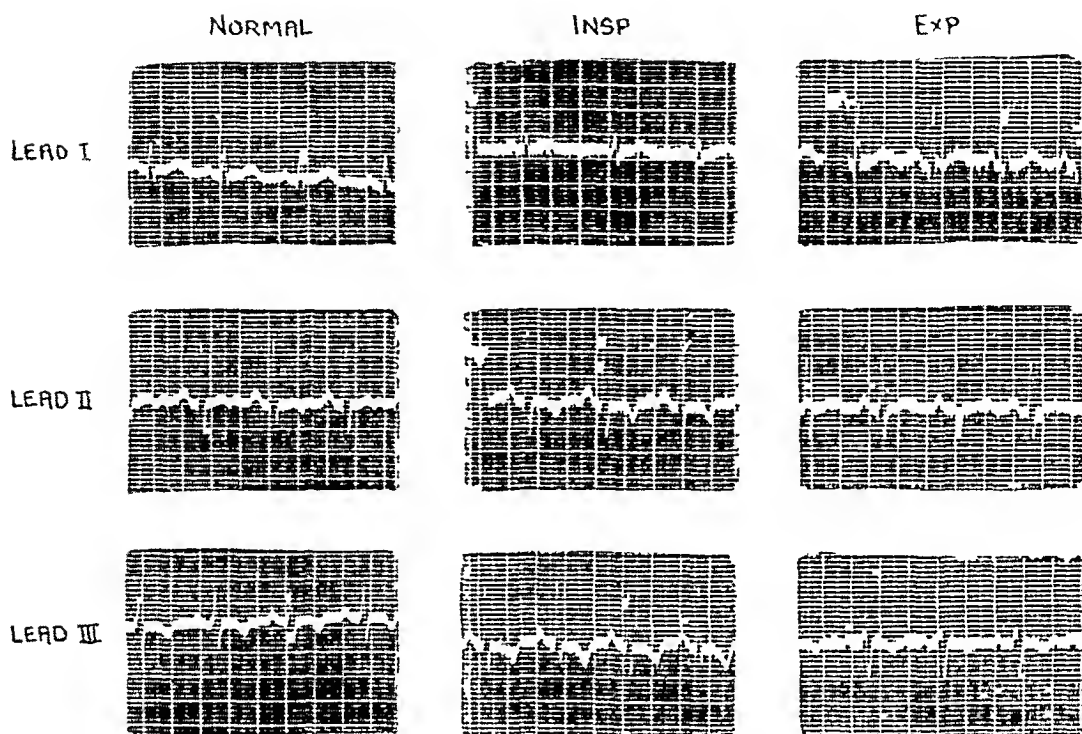

FIG 3 Peculiar T-wave in Lead II markedly altered by deep breathing Apparently normal boy

abnormality Figure 4 is an illustration of functional bundle branch block in an Italian laborer of thirty-five He gave the characteristic history of frequent attacks of paroxysmal tachycardia but no other evidence of heart disease The records were taken a few days apart and show the characteristic features of the condition in the one record and an entirely normal picture in the other In some subsequent records these changes are seen to appear and disappear within a few seconds

Figure 5 illustrates a closely similar condition with a short P-R interval and prolonged intraventricular conduction It is from a patient of Dr Paul D White

When first seen he was an 18 year old boy and a member of a college freshman swimming team He had a history of paroxysmal tachycardia Physical examination was negative except for reduplication of the first sound at the apex of the heart Roentgen-ray revealed no abnormality in the size, shape, or position of the heart and the basal metabolic rate was normal An electrocardiogram taken in 1936, eight years later, showed the same abnormalities and the same decrease in the amplitude of the T-waves after exercise

In a third group of cases transient inversion of the T-waves in Leads I and II without other changes has been observed in the absence of organic heart disease As Graybiel and White³ pointed out, this is often associated with neuro-circulatory asthenia, paroxysmal tachycardia or thyrotoxicosis

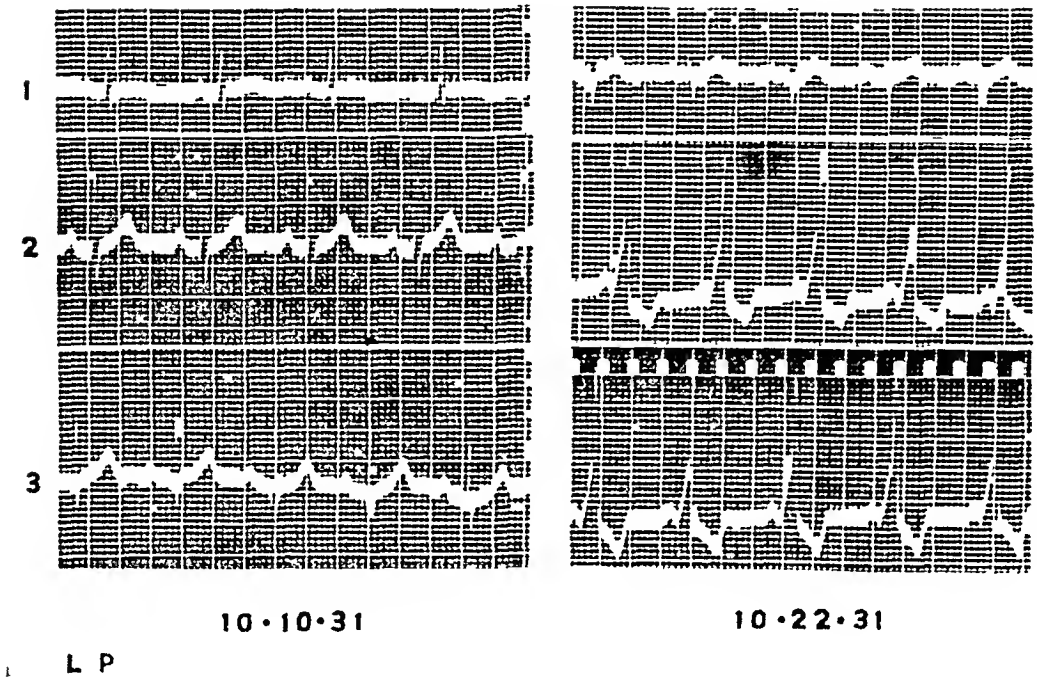

FIG 4 Normal mechanism and "functional bundle branch block" in the same individual

FIG 5 Intraventricular block with short P-R interval in an apparently healthy youth

The following case is an illustration of this type of disturbance

In the fall of 1934, A. P., a 16 year old boy, had presented himself with the story that his local doctor had forbidden him strenuous exercise because of rapid heart action. He himself sometimes felt his heart pound but not particularly when active. He did not know whether the action was rapid or irregular. He had no other complaints. He had had a normal development without rheumatic fever, scarlet fever or chorea.

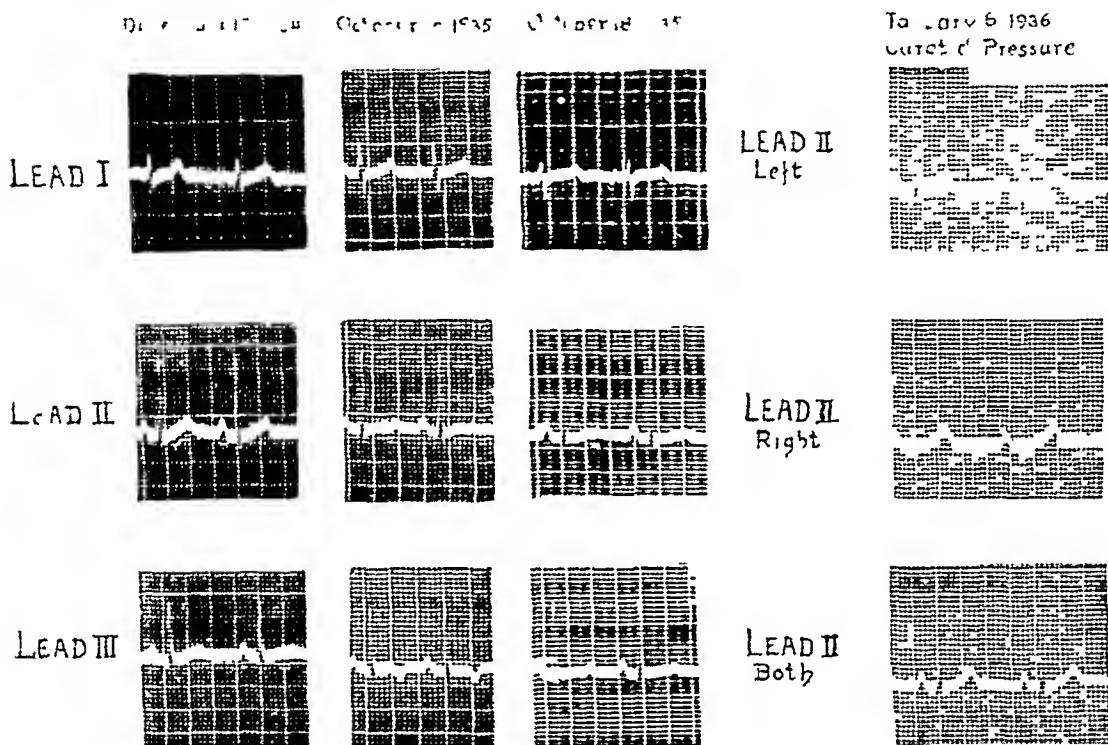

FIG 6 Transient changes in T-waves particularly in Lead II unassociated with any clinical evidence of disease

Physical examination at that time showed no evidence of disease. The heart was not enlarged, the rhythm and sounds were normal, with a rate of 72 at rest. There were no murmurs. The blood pressure was 120 systolic and 65 diastolic. The response of the heart rate and the blood pressure to exercise was normal. A seven foot plate of the chest showed the heart normal in size and shape, and the aorta normal in appearance. Electrocardiogram showed normal mechanism, rate 98. The auriculo-ventricular and intra-ventricular conduction times were within normal limits and all T-waves were upright and of normal shape.

A diagnosis of irritable heart was made and he was allowed to resume strenuous activity—to include football playing. He was seen next in February 1935, five months later, at which time no mention was made of his heart, and physical examination was again negative.

In October 1935, one year after his first visit, he appeared because when warming up on the sidelines of a football game he would feel his heart pound and would be momentarily short of breath. In a few seconds these symptoms would pass, he would enter the game and play hard with no symptoms. He had had an unusually active preceding summer and avowed he never felt better.

Physical examination revealed a normal sized heart, rate 78, normal rhythm, no murmurs, blood pressure 120 systolic and 80 diastolic. The electrocardiogram, however, showed a definite change from that made one year previously (figure 6). The record now showed a peculiar diphasic character to the T-wave in Lead II and a considerable late inversion of the T-wave in Lead III.

This was very disconcerting. Because of our conviction that this boy had no myocardial or coronary disease as suggested by the electrocardiogram we sent him running up and down two flights of stairs. On his return to the laboratory there appeared a slight definite change toward normality. This tendency to change under observation, especially following a speeding up of the circulation confirmed us in our opinion that the electrocardiogram was recording only functional changes, and so he was again sent back to the football field. A check-up on January 6, 1936, after a strenuous athletic season, now showed a completely normal tracing. To test the effect of vagal stimulation on the mechanism, pressure was applied to the left, right, and to both carotid sinuses. No changes in the T-waves were produced by these measures, although the rate was definitely slowed.

The conclusions to be drawn from these experiences are that when isolated electrocardiographic abnormalities occur in the absence of any other signs of heart disease they must be viewed with skepticism. The functional nature of some of these may be demonstrated by appropriate measures such as by exercise, administration of atropine or deep breathing.

DISCUSSION

Such observations as the foregoing illustrate anew the dangers of interpreting an electrocardiogram without full knowledge of all the other clinical features of the case. The testimony furnished by the electrocardiogram can be properly evaluated only when all the evidence is in, or occasionally it will deceive us. It will always tell the truth but never the whole truth.

Now that this delicate instrument of precision is becoming an every day office accessory of the internist, it may be hoped that it will lose some of the aura of infallibility which hung about it in its laboratory days. It may then assume its rightful position, not as a court of last appeal in cardiac diagnosis, but as a very valuable adjunct to physical and roentgen-ray examinations.

PUBLIC HEALTH CONTROL OF SYPHILIS *

By THOMAS PARRAN, JR , M D , Commissioner of Health, New York State,
Albany, N Y

As one after another of the epidemic diseases has declined or disappeared under the impact of public health effort, it is natural that the same technics should be directed against other major causes of sickness and death. Moreover the success of past and current public health measures has engendered the confidence of the tax-paying public which will support extension of community action into fields heretofore reserved to private effort.

These two facts make it inevitable that the public health control of syphilis should be the central problem now faced by health departments. In undertaking any public health measure, those of us responsible for securing and expending public funds must consider the extent of the hazard to health and life, the controllability of the disease, and the cost of effective control efforts.

EXTENT OF THE SYPHILIS PROBLEM

From the mass of conflicting statistics and statements about syphilis, it is difficult to sort out dependable facts. This is due both to the nature of the disease and the different methods of stating its extent. Syphilis often is a subclinical infection with an unrecognized onset. It has periods of latency, and the end-point or cure frequently cannot be determined. Both the past and the present true attack rates are still the subject of conjecture. Although it shortens the life span of its victims, the total effect on mortality is not known.

Moreover, in expressing the amount of syphilis in a community, one may refer to the number of clinically recognized cases which are under treatment at a given time, the attack rate of clinically recognized cases which occur in a specified period, or the findings from serological and clinical surveys among special groups. Since in every community an unknown number of cases are not diagnosed and treated, and since surveys of limited groups are made by serological tests of varying sensitivity, and since such groups are not representative in age, sex, and other respects of the whole population, none of these methods gives a complete picture.

Add to these inaccuracies the geographic, racial, sex, social, and age variation in syphilis prevalence, and the complexity of the problem becomes apparent. In fact, it probably is easier to eradicate syphilis in a population than to determine its exact prevalence and distribution. In spite of these inaccuracies and uncertainties, certain facts are clear and certain conclusions are warranted concerning the extent of the syphilis problem. These facts together indicate that the statement of Sir William Osler, that syphilis ranks

* Read at the Detroit meeting of the American College of Physicians, March 3, 1936

with tuberculosis and cancer as a major cause of death, is as true today as it was when he made it

In upstate New York a census of all cases under treatment by all physicians, hospitals, clinics and other institutions was made in 1927 and repeated in 1930 and 1935. In the last two surveys data were secured also as to the number of new cases which were diagnosed for the first time during the month of April

The total of cases under treatment *increased* from approximately 12,000 in 1927 to approximately 17,000 in 1935 (43 per cent), while cases of early syphilis *decreased* from 3,415 to 2,029 (43 per cent) during the same period

The total of cases diagnosed for the first time in April 1935 was 1,644 which, when compared with 1,899 diagnosed in a similar period in 1930, constitutes a decrease of 19 per cent. Early syphilis cases diagnosed for the first time in April 1935 were 462, as compared with the 1930 total of 854, a decrease of 46 per cent

The prevalence and attack rates in upstate New York as shown by our surveys are much lower than in southern states and in cities with large negro populations, but much higher than in certain mid-western rural areas

Studies by Nelson in Massachusetts show also a decline in new cases of the disease in recent years, but a continued increase in total cases

The decline in early cases in these two states from which recent reports are available suggests that at last the results of control efforts are apparent. The continued increase in the total of cases newly diagnosed impels caution, however, as to full acceptance as yet of this conclusion. A disturbing fact apparent from the data collected in this and other countries is the large proportion of late syphilis in the total of first diagnoses and clinic admissions. In Great Britain, for example, with accurate histories on admission for all clinic cases, more than one-half of the new admissions are cases of late syphilis. Case finding early in the disease leaves much to be desired

Although recent reports from Massachusetts and New York suggest a decrease in new cases of syphilis, the data available to the Public Health Service from the country as a whole do not indicate a decline. From Great Britain and the Scandinavian countries, on the contrary, reliable reports are available showing that syphilis in recent years has declined markedly, and in the Scandinavian countries the disease now shows only a small fraction of its former prevalence. With frank skepticism, I undertook a study last summer of their data, their methods, and results. Three critical colleagues confirm my statement that the Scandinavian reports are genuine. Syphilis there has become a rare disease. In Sweden, with a population of 6,100,000 (almost the same as upstate New York), there were just 431 cases of the disease in 1934, in the first half of 1935 there were only 200 cases. Multiply the population and cases by 20 and the data are comparable with those for the United States. If the rate for Sweden were applied to the whole population of the United States, we would have annually only 8,620 cases. Compare this with the Public Health Service estimates of 420,000. The

rate in Sweden now is only one-tenth of the rate 15 years ago. That inadequate reporting is not a factor is confirmed by the continued high prevalence of gonorrhea, amounting to approximately 12,000 new cases in 1934. This fact, too, makes it clear that medical measures rather than moral restraints have brought about the decline in syphilis.

In Denmark an almost comparable decline has been recorded. In that country all Wassermann tests for the whole country are done in the one State Serum Institute, where complete records have been kept of every examination, positive and negative, during the past 16 years. Denmark has a population of 2,600,000. In 1933 syphilis cases totalled 648. At the peak of the post-war epidemic in 1919 there were 7,024 cases. In Copenhagen the decline has been even greater—from 2,189 to 181. Here, too, the prevalence of gonorrhea has continued high.

In Norway, data for the country outside of the capital, Oslo, are incomplete. In this city, however, the cases per 100,000 population decreased from 360 in 1919 to 30 in 1935.

In Great Britain, where there is no reporting of cases but where a large percentage of the total is treated in public clinics, new admissions have declined by more than one-half since 1920. The 20,692 new admissions to clinics in Great Britain and Wales in 1934 represent an admission rate of 54.3 per 100,000 population. This should be compared with the upstate New York clinic admission rate of 112.6 for the same period.

While the methods in these countries differ in many respects, the provision of public clinic facilities of a good quality, available to all patients, is the factor common to each. In addition, the Scandinavian countries require notification of cases, and treatment is compulsory. In Sweden the careful investigation made of sources of infection is a noteworthy feature.

CONTROLLABILITY OF SYPHILIS

It is not surprising that countries which have undertaken systematic control measures have gotten results, since the facts concerning syphilis argue for its controllability. The causative agent is known, a diagnosis can be made as soon as the case is infectious, we have serological tests which will discover otherwise latent cases, in the arsphenamines, we have remedies which will speedily sterilize the infectious case. Unlike such diseases as typhoid fever, syphilis is spread singly from person to person by intimate contact. The source of infection and those exposed usually are known to the patient.

Compare these facts with tuberculosis, a disease which has declined by two-thirds during the past 30 years. For tuberculosis, there is no specific method of cure or of rendering the patient non-infectious. Diagnosis of the early case is costly and difficult. The infectious agent is widely disseminated in the population. In spite of these greater difficulties, the practical control and even eradication of tuberculosis in this country is a goal.

clearly in sight. The great difference between these diseases, however, is that, in the case of tuberculosis, we have promoted public knowledge of the disease, mobilized the profession, created public facilities, and organized community programs of control.

In spite of knowledge concerning syphilis, which seems adequate for control, we must not lose sight of certain biologic facts which make the problem difficult: the obscure nature and transitory character of the initial lesion, the tendency of the disease to relapse under inadequate treatment, the possibility of second and completely blind infections, the unknown rôle of the chronic carrier as a factor in spread, and the possible reversion of the organism to a more virulent form. These factors are important and need further study. Since our present methods do not appear to have brought about a decline in syphilis prevalence, it is fair to ask if we have neglected to use to best advantage all available weapons.

EPIDEMIOLOGICAL APPROACH

During recent years, the studies of Munson in New York and of Smith and Brumfield in Virginia demonstrate clearly that, by the use of the epidemiological method, undiscovered sources of infection can be found and brought under treatment. Evidence has accumulated also which shows that syphilis does not spread evenly in the population, but that it is kept alive and spreads chiefly by a series of small epidemics. Munson traced more than 30 such local outbreaks, averaging four or five cases each, most of which were not under treatment. Smith and Brumfield have shown that from 157 new cases of early syphilis 345 contacts or potential sources were named (representing 278 persons), of whom nearly one-half were located and brought under treatment. Of these cases, all were in the early infectious stage of the disease and had not been under treatment previously. These methods have been tried in New York State in recent years with results sufficiently gratifying to warrant the state-wide application of the principle. In the epidemiological method, we have an unused instrument for the control of syphilis which, in my opinion, is of as much value as the Wassermann test or the arsphenamines.

NEW YORK PROGRAM

Before starting our program, it was discussed with the Public Health Committee of the State Medical Society, and many details worked out with the advice of its members. As finally agreed upon, it was approved by this committee and the Executive Committee of the State Society.

Our syphilis control program has four major objectives: (1) The notification of cases, (2) intensive and complete investigation and supervision of sources of infection, cases and contacts, (3) the provision of facilities for adequate diagnosis and treatment, (4) professional and public education.

In New York City essentially the same plans are being developed but modified to fit the particular needs of that large metropolis

For administrative purposes, the State (outside of New York City) is divided into 33 districts comprising the 12 cities of more than 50,000 population, the five county departments of health and 16 state health districts. The program is carried out by the city and county departments of health with state-aid if State standards are met. Outside of the large cities and the five counties with departments of health, state-aid is given to local clinics, but reports are made directly to the state district office, and state personnel is used for the epidemiological work.

CASE REPORTING

The starting point is a state-wide system of approved laboratories. Whenever a physician diagnoses or suspects the existence of syphilis or of another communicable disease, an appropriate specimen must be sent to an approved laboratory accompanied by information as to whether the specimen is for diagnosis or treatment control, the stage of the disease, and other pertinent facts. The laboratories are required to submit copies of all positive reports to the local health officer or the state district officer. Physicians are required to make a case report of each case of syphilis, giving sex, date of birth, and address, but it is not necessary for the name to be given. Thus the identity of the cooperative private patient is safeguarded. These reports are checked against the positive laboratory findings to insure completeness.

Physicians are required, however, to report by name any lapsed infectious case, and health department nurses are available to follow up such lapsed cases and return them to their physician for further treatment. Another service is the furnishing of free arsphenamines and bismuth to private physicians for private patients, as well as to clinics.

When a case of smallpox seeks treatment, the first impulse of any good physician is to call the health officer. Is it too much to hope that we can create the same interest in the source of early syphilis? Is it unreasonable to ask that an obligation to the community no less than to the patient be assumed in this as in other infectious diseases?

All cases of syphilis are classified into three categories: (a) early syphilis (less than one year since onset), (b) other potentially infectious cases, (c) late non-infectious cases. The term "potentially infectious" is applied to the following types of cases regardless of the presence or absence of visible lesions:

- 1 All patients with acquired syphilis who have received less than 20 injections each of an arsphenamine and a heavy metal, or equivalent treatment, until five years have elapsed since onset.

- 2 All female patients with acquired syphilis inadequately treated, until the menopause has been reached.

3 All patients with early congenital syphilis

Efforts to determine sources of infection are limited to early syphilis. Investigation of contacts, however, and supervision of cases are extended to include also all potentially infectious cases, but with major emphasis on persons 15 to 30 years of age and cases of less than 2 years' duration.

EPIDEMIOLOGICAL WORK

In each of our 33 districts a trained medical officer with one or more nurses and sufficient clerical assistance is responsible for the syphilis epidemiological work. When a physician reports a case in private practice, the medical officer goes or telephones to the physician himself and asks him either to permit the health department to investigate the case or to make this investigation himself in order to locate, if possible, the source of infection. If the physician elects to assume the responsibility, he again is given the choice of getting the source of infection and contacts under treatment, or permitting the health department to do it. After six months' trial in our larger cities, I am happy to report that in practically no instance have the physicians failed to cooperate. It is beginning to be apparent, however, that the record of the private physician in ascertaining sources of infection is not as good as that of the trained epidemiologist. An epidemiological record card is executed for each early case, which is comparable in completeness to the records used in the investigation of typhoid fever, for example.

No investigation of an early case is acceptable unless the source of infection is found, or unless satisfactory evidence is submitted to establish beyond reasonable doubt that this individual cannot be identified and located. Results to date indicate that, in from 20 to 30 per cent of all cases of early syphilis, the source of infection can be located and brought under treatment.

APPROVED CLINICS

An essential part of our program is to elevate the quality of clinic service. Those clinics which meet prescribed standards are designated as "approved clinics"*. Until recently most physicians have served in syphilis clinics without compensation. Provision now is made for paying all such physicians. The rate of payment varies, but averages about \$10 per session.

The following classes of patients are eligible for treatment at clinics irrespective of whether or not they are residents: (a) any patient for initial diagnosis and emergency treatment if found to be infectious, (b) any patient

* Standards for "approved clinics" may be summarized as follows. They must be conveniently located with adequate quarters and separate waiting rooms or separate sessions for men and women. Records containing prescribed minimum information must be kept. The treatment of early syphilis must be a continuous system and in conformity with modern accepted practice. Spinal fluid examinations must be performed whenever possible before the patient is ready for discharge. In the larger centers facilities for cardiovascular and other examinations must be provided. Each clinic must have adequate medical, nursing and clerical personnel. In each city daily clinic service must be provided with at least one evening session per week, and facilities must be provided to determine the financial status of patients.

unable to pay a private physician for treatment, (c) any patient referred by physician for consultation, such case to be returned to the referring physician with examination reports and advice for further treatment. The acceptance of non-resident patients and the introduction of consultation for the general practitioner as a function of the clinic are new features.

Definite requirements are made concerning the reporting of cases which lapse for more than one week, and an automatic procedure of follow-up is established. Wherever possible, improvement of existing clinics attached to hospitals is sought, rather than the setting up of separate clinics.

There are approximately 120 syphilis clinics in upstate New York, and we are now engaged in studying these clinics and specifying the changes necessary to qualify for approval and state aid.

In the centers of population too small to support a clinic service, the local health officer is required by law to provide treatment of any person with a venereal disease unable to pay a private physician. For this service he is entitled to payment at rates comparable to those paid for other public medical services.

EDUCATION

Major emphasis thus far has been put upon professional education. This includes the training of physicians and nurses in the public health and clinical aspects of the problem.

An extension course in social hygiene was given to more than 1 000 public health nurses two years ago. This was followed last year by a summer course at Syracuse University for 70 nurses selected for this special work in clinics and health departments. Another such course will be held this summer for a larger group. In addition, we are assembling a corps of young physicians and giving them special training in public health and in the epidemiological method of syphilis control. A number of the leading syphilologists in the State are assisting us on a part-time basis as consultants in promoting the organization and quality of clinic service, and in professional education.

A series of regional institutes will be held this year primarily for clinic physicians. Attendance is promoted by compensating these physicians for time lost from practice. These institutes will be open to other interested medical men. Moreover, a number of County Medical Societies are holding for practitioners postgraduate courses in syphilis therapy. By these several methods we hope to compete with the pharmaceutical "detail men" in teaching the general practitioner how to treat syphilis.

For several years we have had the active cooperation of the State Committee on Tuberculosis and Public Health in promoting public interest and knowledge of syphilis. Some progress has been made in breaking down the barrier of public ignorance and apathy. Our Governor and Legislature have been willing to provide funds. They have been convinced that the cost of a syphilis control program is less than the cost of continued neglect. The

newspapers, and recently the National Broadcasting Company have permitted the word syphilis to be used. Health departments and physicians must seize the opportunity and be prepared to furnish needed information. Yes, the word *syphilis* must be spoken, heard, printed, understood.

SUMMARY

The prevalence of syphilis in the United States continues to be high, and its control is the most urgent public health task with which health authorities are confronted.

The Scandinavian countries, and Sweden in particular, by organized national effort have accomplished a modern miracle in medicine—the practical eradication of syphilis.

The epidemiological method of locating infectious sources is an unused weapon, but potentially as valuable as the arsphenamines and serodiagnosis.

New York State is undertaking a serious state-wide control program with full cooperation of the medical profession.

What the health department is doing in New York can and should be done in every State. Available Federal funds for Social Security make it possible.

In the public health control of syphilis, the members of the American College of Physicians have an opportunity this year, each in his own community, to sponsor and support a great work for a high purpose, with assurance of good results to the public.

THE CLINICAL ASPECTS OF AMYLOIDOSIS¹

By ELI MOSCHCOWITZ, *New York, N Y*

INTRODUCTION

FROM the nosological aspect generalized amyloidosis has not received its due recognition. It has hitherto been largely viewed as an ominous sequel of chronic suppuration, with cachexia, anemia, swelling of the liver and spleen, and albuminuria as the most prominent clinical expressions. In recent years, new data have been established which have widened the diagnostic basis of this disease. These are the recognition (1) of primary amyloidosis, (2) of so-called atypical amyloidosis, (3) of the relation of general amyloidosis to "nephrotic," or better termed, hypoproteinemic states, and (4) the establishment of the Bennhold Congo red test. These viewpoints and the opportunity to observe a considerable number of cases of amyloidosis, both primary and of unusual etiology, have stimulated this study.

A MORBID ANATOMY

The amyloid substance is deposited in the mesenchyme and more particularly in the reticular and collagenous tissues of the periglandular and pericapillary structures. The reticulo-endothelial system is usually profoundly affected. Epithelial tissues are comparatively free from amyloid invasion. Friedreich and Kekulé¹ first showed that the amyloid substance was protein in nature. For a long time, amyloid was supposed to be a compound of protein with chondroitin-sulphuric acid, but Hanssen² who studied amyloid in pure form found no chondroitin-sulphuric acid. Eppinger³ in his chemical analysis of a solitary amyloid mass, found within a liver, determined that the dried material contained purines, diamine acids and much tyrosine. There was no carbohydrate, phosphorus or sulphur. Apparently amyloid is not always uniform in chemical composition, because in some of the atypical forms of amyloidosis the staining reactions are bizarre (Lubarsch⁴).

The organs most frequently involved in generalized amyloidosis are, in the order of frequency, the spleen, liver, kidney, suprarenals, and lymph nodes. This incidence corresponds to that found in experimental amyloidosis (Jaffe⁵) and to that found in horses used in antitoxin production (Doerken⁶). Less frequently amyloid is deposited in the intestines and pancreas. Lubarsch never saw amyloid in the brain. In the atypical form of amyloidosis amyloid has been found in almost every organ of the body: the tongue (Pick⁷), the bone marrow (Gerber⁸), the skin (Konigstein⁹),

* Received for publication April 18, 1936

From the Service of Dr. B. S. Oppenheimer, Mt. Sinai Hospital, New York City

the muscles (Warren¹⁰), the heart (Budd¹¹), and in tumors (Weber,¹² Glaus,¹³ Hueter¹⁴)

The detection of amyloid in tissues is entirely colorimetric, and depends upon the histological reaction of this substance to the methyl violet stain and to iodine

Etiology That amyloidosis follows chronic suppuration is well known. Of 112 autopsies in Montefiore Hospital in which amyloid was present, Rosenblatt¹⁵ found that in 100 there was an associated tuberculosis. This represented 25 per cent of all patients dying with this disease. Of the remaining 12, three had no apparent cause, two were associated with carcinoma of the lung and secondary suppuration, one was associated with a chronic osteomyelitis, three with pyelonephritis, one with carcinoma of the stomach, one with leukemia and one with tabes dorsalis. Of 100 cases of amyloid disease involving the kidney, reported from the Philadelphia General Hospital by Dixon,¹⁶ 78 per cent were associated with tuberculosis of the lungs or bones, 9 per cent with malignant tumors, 5 per cent with empyema, 2 per cent with chronic arthritis, 2 per cent with osteomyelitis, 1 per cent with bronchiectasis, 1 per cent with lung abscess, and in 3 per cent the cause was unknown.

At Mt Sinai Hospital, amyloid change was found in 42 autopsies from the year 1916 to the present. Of these, 11 were caused by tuberculosis of the lungs, 10 by lung abscess or chronic bronchiectasis, three by chronic osteomyelitis, four by neoplasms, two by Hodgkin's disease and one each by subacute bacterial endocarditis, lues of the aorta and liver, chronic ulcerative colitis, tuberculous osteomyelitis, tuberculous pyonephrosis, tuberculous entero-colitis, perinephritic abscess, general tuberculosis, tuberculous coxitis. Two cases were primary. Of the total, 16 were caused by tuberculosis. This report does not include clinical cases of amyloidosis observed at Mt Sinai Hospital during this time, but it represents a valid cross section of the incidence in relation to etiology.

There is an interesting association between amyloid and myeloma. Magnus-Levy¹⁷ in 1931 collected 19 such cases. The amyloidosis may be generalized but more often it is localized in unusual sites, such as the muscles, the dura mater, the abdominal wall, the intestines, the bones, tongue, esophagus, etc. Magnus-Levy regards the amyloid substance and Bence-Jones protein as chemically related. He found small quantities of Bence-Jones protein in myeloma tissue especially in crystalline form. He does not believe that the Bence-Jones protein is transported. He also found Bence-Jones protein in the body fluids, in the blood serum, in serous effusions and in the bone marrow, and only rarely in the liver, spleen and kidneys. The reason it is found only in small quantities in these fluids is, he believes, because it is rapidly formed and excreted. Bell¹⁸ reports a case of amyloid with myeloma in which the extensive amyloid infiltration of the muscular wall of the intestine caused obstruction.

The association of generalized amyloidosis with malignant blastomata is not uncommon. Usually the tumor shows extensive necrosis. Lubarsch saw amyloid 20 times in a series of 398 cancers, and in a large percentage of experimental mouse cancers. We are not referring here to the cases of localized microscopic or extensive amyloid infiltration of blastomata, usually myeloma, that have been reported (Weber, Glaus, Hueter).

The occasional association of amyloidosis with non-suppurative maladies is not always to be regarded as cause and effect. For instance, the simultaneous occurrence of chronic deforming arthritis and amyloidosis is reported too infrequently (Dixon, Rosenblatt, Perla and Gross¹⁹) (cases 1 and 2 in my series may be included) to be more than an accidental association. In all likelihood, the arthritis is not the cause of the amyloidosis, rather both conditions are simultaneous reactions to the same insult.

Primary amyloidosis forms a not inconsiderable section of all reported cases, especially of the localized or atypical variety, and offers a difficult problem for diagnosis. Such primary cases comprise a distinct nosological entity which requires serious consideration.

CASE REPORTS

Case 1 S. H., aged 57, was admitted to the service of Dr. B. S. Oppenheimer, September 14, 1934. The previous history was irrelevant. Four years ago, following the onset of menopause, the patient developed pain, swelling and stiffness of the joints, many of the joints showed an effusion. Subsequently the joints of the hands and feet became deformed. During the past three years there has been swelling of the lower extremities and increasing loss of weight. Five weeks previous to hospitalization she developed anorexia, nausea and vomiting and she also noted that her skin was becoming dark. On examination, in addition to the pigmentation of the skin, there was a bilateral conduction auditory defect, yellowish exudates in the right fundus, a heart enlarged to the left with sounds of poor quality, a systolic murmur was heard over the precordium but loudest at the base, the blood pressure was 110 systolic and 60 diastolic. The peripheral vessels were not sclerosed. The liver was enlarged, reaching 3 cm. below the costal margin. The muscles of both hands were atrophic, there was ulnar deviation, spindle shaped fingers and swelling of the metacarpal joints. The knee joints were red, swollen and tender. There was tenderness of both shoulder joints, and slight edema of both lower extremities. The hemoglobin was 60 per cent, red blood cells 3,400,000, white blood cells 8,000, polymorphonuclears 50 per cent. The urine showed a specific gravity of 1.014 after the concentration test, there was a heavy precipitate of albumin on boiling and casts were present. The blood cholesterol was 290 mg. The urea 27 mg. The total blood protein was 6.2 per cent, of which the albumin fraction was 2.3 per cent and the globulin 3.9 per cent. The Congo red test showed 70 per cent tissue retention. A diagnosis of primary amyloidosis was made. Liver extract was given intramuscularly and by mouth. For a while there was some general improvement. An examination one year later revealed no appreciable change from her previous condition.

Summary A woman of 57 with a history of deforming general arthritis of four years' duration, the onset of which was followed shortly by symptoms of the so-called nephrotic syndrome with anemia and weakness and simultaneous enlargement of the liver and spleen. The Bennhold Congo red test confirmed the clinical impression that the case was one of generalized amyloidosis. No cause was discoverable. One year later the condition of the patient was unchanged.

Apparently the association of amyloidosis with chronic arthritis is not as rare as generally regarded. The following instance shows that it may occur even in early childhood.

Case 2 A child, aged $2\frac{1}{2}$ years, was admitted to the service of Dr. B. Schick on April 18, 1933 and discharged January 2, 1935. She had suffered with convulsions since the age of one. Shortly after the last convulsion pain in the left thigh and knee appeared followed by pain in the left elbow. Fever appeared two weeks before admission.

On admission she had a temperature of 101.6° F. There were stiffness and tenderness of the lower cervical spine. The left wrist was swollen, hot and tender. The left ankle was swollen and tender. The liver and spleen were not palpable. A soft systolic murmur was heard in the fourth interspace, not transmitted. The urine was normal. The hemoglobin was 61 per cent, red blood cells 3,900,000, white blood count 18,800 with a normal differential count. The sedimentation rate was 31 minutes. The electrocardiogram showed sinus tachycardia. Roentgen-rays of the joints showed no pathologic changes.

For the next nine months the child ran a febrile course, then she became afebrile. The fever reached 104° and she had occasional chills. Blood cultures on several occasions proved sterile. There was progressive loss of weight. Roentgen-rays of her knees taken four months after admission showed marked swelling of the soft tissues with some periosteal thickening of the upper end of the right ulna. A roentgenogram of the chest showed nothing abnormal. The use of typhoid vaccine and removal of the tonsils had no effect upon the progress of the disease. About nine months after admission the liver became palpable two fingers' breadth below the costal border. The urine contained large amounts of albumin. A Congo red test showed 50 per cent retention at the end of one hour. There was 65 per cent excretion of phenolsulphonephthalein at the end of two hours. The concentration of urine was normal. The sedimentation time varied between 5 and 15 minutes. A Congo red test done eight months after admission showed 100 per cent retention. Roentgen-rays about this time showed marked atrophy of all the bones in both knees. The epiphyses were large and irregular, and there was considerable calcified material between the epiphyses. Wassermann tests were negative.

Case 3 C. B., a woman, aged 56 years, was admitted to the hospital (to Dr. B. S. Oppenheimer's service) January 28, 1934. One year previous to her admission she had noted red blotches on the right side of her neck. These lesions were evanescent. However, during the last six months the blotches appeared more frequently, became more extensive, and spread to the left side of the neck, lower eyelids and trunk. They were dark red and irregular in shape. During the past two years she had noticed blood on her handkerchief on blowing her nose. About three months ago while eating she noticed a blue blister beneath her tongue which burst and bled for half an hour. She estimated the quantity of blood lost as about a cupful. There was marked anorexia, and the patient had lost 11 pounds in the four month period previous to admission. She had experienced attacks of precordial oppression and dyspnea on exertion. Palpitation was severe and frequent. She had had numbness of the fingers for the past two years, and for six months sensations of pins and needles in her fingers.

Examination showed a thin, gray-haired woman with cyanosis of the lips. There were arteriosclerotic changes in the vessels of the fundi. The uvula was swollen and ecchymotic, and there were numerous groups of large petechiae on the buccal mucosa, some of which had white centers. The chest was emphysematous and the dorsal spine kyphotic. The lungs were clear. The heart was normal except for frequent extrasystoles. The blood pressure was 140 systolic and 80 diastolic. The liver was

palpable to the umbilicus, and was unusually hard and firm. The spleen was enlarged to three fingers below the free costal border. On the left side of the neck, on the eyelids, and in the right groin there were large purpuric spots. There was no lymphadenopathy.

The hemoglobin was 80 per cent, red blood cells 5,000,000, platelets 230,000, white blood cells 12,000, polymorphonuclear neutrophils, 44 per cent, lymphocytes 54 per cent, monocytes 1 per cent and eosinophils 1 per cent. The tourniquet test was negative. The brom-sulphthalein and galactose tolerance tests gave normal results. The urine on repeated examinations contained abundant albumin, a few white blood cells, hyaline casts, and on one occasion an amyloid cast. There was no Bence-Jones protein in the urine. Roentgenologic studies of the gastrointestinal tract failed to reveal any lesion. Roentgenograms of the chest showed only a hypertrophy of the left ventricle. Roentgenograms of the bones revealed no lesion. A Congo red test showed 100 per cent tissue absorption at the end of one hour. In view of the fact that no other cause for the symptoms was ascertainable, the diagnosis of primary generalized amyloidosis was made. While in the hospital she had repeated crops of cutaneous hemorrhages. On one occasion she had frank blood in the stool, and sigmoidoscopy revealed numerous petechial hemorrhages in the rectal and sigmoidal mucosa. The blood fibrinogen was 350 mg. The blood protein was 7.8 per cent, of which 4 per cent was albumin and 3.8 per cent globulin. The cholesterol was between 340 and 375. The Van den Bergh reactions were normal. The blood Wassermann test was negative. The sedimentation time was 23 minutes.

She was given liver extract intramuscularly, 2 c.c. twice a week. The patient left the hospital on March 7, 1934 and died three weeks later. Her private physician's diagnosis of the cause of death was "uremia."

Summary A woman, aged 56 years, showed purpuric lesions of the skin and mucous membranes for one year. The liver and the spleen were considerably enlarged, there was marked albuminuria, a normal blood pressure, a normal blood protein with an elevated blood cholesterol. The diagnosis of amyloidosis was made and confirmed by the Congo red reaction which showed 100 per cent absorption.

Case 4 L. C., male, aged 38, admitted to the service of the late Dr. N. E. Brill, September 25, 1923. The family history was irrelevant. Twenty years before he had had a chancre and four years before a left-sided "pleurisy" which lasted two weeks. For 10 years he had had occasional frontal headaches. Five years prior to admission he noted dyspnea on exertion. This gradually increased and recently he had suffered from precordial pain when he hurried. About two months before admission his feet began to swell. For the past week he had had choking sensation, dyspnea and swelling of the abdomen. His ears had begun to discharge two months before entry to the hospital.

On examination he presented a diffuse anasarca with edema of the feet, hydrothorax and ascites. The heart was somewhat enlarged, with a short systolic murmur at the apex. The blood pressure was 160 systolic and 50 diastolic. The blood showed a moderate secondary anemia. The temperature was 100.2° F. and the pulse varied between 92 and 120. The knee jerks were absent. The urine contained abundant albumin and many hyaline casts. The blood urea nitrogen was 14 mg. per 100 c.c., cholesterol 170 mg., glucose 200 mg., and carbon dioxide 46.2 volumes per cent. The blood Wassermann test was negative. He died the day following admission in pulmonary edema.

Autopsy The tracheo-bronchial lymph nodes were anthracotic. Both pleural sacs contained one liter clear fluid. The lungs showed edema and passive congestion. The pericardial cavity contained 100 c.c. of clear fluid. The musculature of the heart was dark brown and showed marked fatty changes. The mitral valve was thickened. The coronary arteries showed slight arteriosclerosis. The aorta showed a

few arteriosclerotic plaques in the arch and in the sinuses of Valsalva. The abdomen contained 1.5 liters of clear fluid. The liver was congested and fatty. The spleen was enlarged, deep red and showed an increase in fibrous tissue. The adrenals were normal. The pancreas was fibrotic. The kidneys were large, the capsules stripped easily and the cut surface was smooth and brown. The glomeruli were hardly visible. The microscopic examination showed passive congestion of the lung and liver, and diffuse amyloid change in the liver, spleen, kidneys and adrenals.

It seems rather strange in view of the frequency of chronic ulcerative colitis that amyloidosis has hitherto not been reported as a sequence, as in the following case.

Case 5 F P, aged 48, was admitted to the service of Dr B S Oppenheimer November 7, 1931 and died January 17, 1932. She gave a history of three operations for rectal stricture. Three months before admission her legs and abdomen began to swell.

The patient was emaciated and presented a large liver, a purulent discharge from the rectum and edema of the back and legs. The blood pressure was 134 systolic and 80 diastolic. The hemoglobin was 48 per cent, red blood cells 2,650,000, white blood cells 2,600, of which 77 per cent were polymorphonuclears. The urine contained large amounts of albumin. The stools gave a strongly positive test with guaiac. The Congo red test showed a retention of 29 per cent. The blood urea was 14 mg, the blood glucose 75 mg, the cholesterol 165 mg per 100 cc. The blood Wassermann test was negative. The blood serum proteins were 4.6 gm of which the albumin fraction was 2 and the globulin 2.6 gm. Sigmoidoscopy revealed a granulomatous mass involving the lower rectum and the anus, the posterior vaginal wall was also involved. The remainder of the gastrointestinal tract was normal by roentgen-ray. The chest was normal. A barium enema revealed marked constriction of the mid-sigmoid with fistulous communication between the sigmoid and ileum. A colostomy was performed but the patient continued to fail and she died a short while thereafter.

Anatomical diagnosis Chronic ulcerative stenosing proctitis with multiple fistulae, chronic sigmoiditis and colitis (descending colon), chronic cystitis, terminal ileitis. Amyloidosis of the kidneys. Dilatation of the right auricle and ventricle, broncho-pneumonia of the left upper lobe. Thrombosis of the left pulmonary artery, chronic infectious swelling of the spleen. Pyelonephritis. Hydrothorax. Perihepatitis and perisplenitis. Organizing emboli of left pulmonary artery, pulmonary infarct.

Summary A woman of 48, with a long standing chronic colitis and terminal ileitis with multiple intestinal fistulae, who developed a nephrotic syndrome caused by renal amyloidosis. The Congo red test showed a retention of the dye within the normal range, proving that the test is not infallible. The amyloidosis was limited to the kidney.

Case 6 A woman, aged 23, admitted to the service of Dr G Baehr, had an ileostomy performed seven years before for ulcerative colitis. Following this she was readmitted to the hospital on several occasions, once for intestinal obstruction with nausea and vomiting which subsided within several days and once with an ischio-rectal abscess which was incised and drained and which continued to drain up to the time of admission. She had also developed a recto-vaginal fistula and a peri-rectal abscess. The ileostomy functioned well and she was able to carry on a somewhat restricted life. One year before this admission she vomited about once a month. The vomiting was accompanied by mild abdominal discomfort and was not profuse. Her last bout of vomiting occurred two weeks before admission. Nine days before admission she noted oliguria and two days later complete anuria. At that time she began to vomit profusely and continued to vomit until the time of admission. Head-

aches and dizziness accompanied this spell of vomiting. Physical examination showed a poorly developed, poorly nourished female, appearing acutely ill. The breath was uriferous. The heart sounds were of fair quality. The blood pressure was 90 systolic and 70 diastolic. An ileostomy of the right lower quadrant, apparently functioning well, was present. There was an anal stricture not admitting the examining finger. There were discharging granulating ulcerations of the right inguinal and right ischio-rectal regions. The extremities were cold and clammy. There was a positive Chvostek sign. The hemoglobin was 36 per cent, red blood cells 2,100,000, white blood cells 7,200. Her urine showed abundant albumin and innumerable casts. The urea nitrogen on admission was 178 mg, calcium 63 mg, phosphorus 77 mg, chlorides 350 mg per 100 c c. The CO_2 49.5 volumes per cent. The electrocardiogram showed sinus tachycardia with tendency to left ventricular preponderance. The sedimentation time was 7 minutes. The phenolsulphonephthalein test showed no excretion. Scrapings from the fistulae showed no evidence of tuberculosis. The fundi were normal. The von Pirquet test was negative. The Mantoux test was positive with a 1/1000 dilution. A concentration test of the urine showed a maximum concentration of 1012. The patient was given intravenous glucose and saline solution, and calcium gluconate. Her urinary output gradually increased, signs of tetany subsided, the blood urea gradually fell to 70 mg per 100 c c. Her blood chlorides rose to 550 mg, calcium rose to 104 mg, phosphorus fell to 43 mg, the total protein was 63 per cent, albumin 23 per cent, globulin 31 per cent. Her urine, however, continued to show abundant albumin with occasional hyalin and granular casts and many leukocytes. Her blood pressure ranged from 64 systolic and 48 diastolic to 86 systolic and 46 diastolic.

The Congo red test showed 100 per cent retention on one occasion and 95 per cent retention on another occasion. In retrospect the clinical picture was explained on the basis of a long standing chronic oliguria with associated nitrogen retention producing vomiting from time to time and finally reaching such a stage that vomiting became continuous with resulting anuria. A vicious cycle by loss of chlorides caused an extreme azotemia with peripheral collapse.

Whether or not an intercurrent glomerulonephritis was present is merely conjectural. The urine was free of lead and arsenic. The patient was given liver extract and a transfusion. There was a moderate improvement in her general condition, and she was discharged from the hospital one month after admission.

THE MECHANISM INVOLVED IN THE PRODUCTION OF AMYLOIDOSIS

Experimental Amyloidosis In what manner do suppuration and tissue necrosis bring about the production of amyloid substance in the mesenchyme? Some light has been thrown upon the problem by the successful experimental production of amyloid. Credit for the first valid experimental production of amyloidosis belongs to Kuczynski²⁰ who in 1922 produced amyloid disease by the injection of 5 per cent sodium caseinate over prolonged periods into mice, he also found that it could be produced by excessive feeding of such protein. Since then Kuczynski's work has been repeatedly confirmed, especially by Smetana,²¹ Jaffe,²² Lucke, Letterer,²³ and Grayzel, Jacoby and Warshall²⁴. Jaffe carried on his work on an extensive scale. He employed a 3 per cent solution of sodium caseinate in normal sodium chloride solution injected into mice every few days. After the sixtieth injection the results were uniform, so that he could always find amyloid in the spleen. After the eightieth injection the amyloid was

distributed in most of the parenchymatous organs, i.e. the spleen, the liver, the kidneys, suprarenal glands, the lymph glands and the intestines. Eventually every organ was affected except the skin and the central nervous system. He obtained the same results by the repeated injections of sterile human serum so that he regards amyloidosis as due to chronic protein poisoning. Jaffé and others have found a crystalline form of amyloid in experimental animals which apparently is only rarely found in human amyloidosis. He found that the blood of his experimental animals showed a normal refractometer index and a normal hydrogen-ion concentration.

Grayzel, Jacoby and Warshall found that diet influenced the production of amyloidosis. An adequate diet but one containing an abundance of vitamins A and B will retard the development of experimental amyloidosis. They also noted the resorption of amyloid in animals in the early stages if powdered whole liver was added to the diet. No resorption was noted in the advanced stages. It is upon these observations that the treatment of amyloidosis by liver is based.

Letterer produced amyloid not only with sodium caseinate, but with gelatine, egg albumin, cereal albumin, nuclein and peptone. He also implanted portions of normal spleen and kidneys and occasionally obtained amyloidosis. Occasionally he produced amyloid with injections of selenium, especially if the animals were fed little water. The ingestion of water seemed to have an influence on the production of amyloid even with sodium caseinate injections, water restricted animals required a much smaller dose than those who were given water freely.

In this connection, the findings of Doerken and Arndt²⁵ are pertinent. They studied the incidence and histological reactions of amyloid in 100 horses employed in the production of antitoxin. They found that 60 per cent of these animals showed amyloidosis, and the incidence of affection of the various organs parallels closely those observed in human and experimental amyloidosis. The animals had been used for the production of different varieties of antisera for two and a half to 54 months. Before the eighth month, amyloidosis was never found, after the sixteenth month nearly always and after the twenty-first month always. Curiously, the horses employed for the production of scarlet fever antisera showed a greater incidence of amyloidosis than those used for productions of tetanus or diphtheria antitoxins. Unfortunately no observations upon the total protein content of the blood of these horses were made, but it is interesting to note, as upholding Letterer's contention, that hyperglobulinemia is the direct cause of amyloidosis, that Reitstotter²⁶ found in serum treated horses an increase of globulin, sometimes up to 100 per cent at the expense of the albumin fraction.

The changes noted by many observers in the blood protein when protein is added to the body economy either parenterally or otherwise are significant. Moll²⁷ found an increase of globulins in the blood after repeated injections of protein gelatin and killed bacteria. Rowe²⁸ found an increase in blood

proteins on a continued high protein diet, and Doeir and Berger ²⁹ observed high blood proteins in rabbits repeatedly injected with horse serum, Berger ³⁰ found that this increase is at the expense of the albumin with a corresponding rise in the globulin fraction. In his experimental animals, Letterer found only a slight increase in the total blood and globulin protein.

Clinically a hyperproteinemia has been found but rarely in generalized amyloidosis. Koref ³¹ in a case of amyloidosis secondary to tuberculosis found the blood proteins 10.89 gm per 100 cc with an albumin-globulin ratio of 20:80. There was a slight rise in the total fibrinogen. These figures are remarkable in view of the fact that in this case there was a free proteinuria. Petschacher ³² found hyperproteinemia and hyperglobulinemia in a case of amyloidosis consequent to an ulcerating tuberculosis.

As another link in the chain of his evidence, Letterer found that there is a close affinity in the molecular content of carbon, hydrogen, nitrogen and sulphur atoms between amyloid and globulin.

Until systematic studies of the blood proteins in human and experimental amyloidosis have been made, all that can be said for Letterer's contention is that it is highly suggestive. The fact that low blood proteins are found frequently in human amyloidosis does not invalidate his views because it may easily be conceived that when the amyloidosis is so far advanced as to involve the kidneys and cause proteinuria, a previously high proteinemia may be converted into a deficiency. As far as our present knowledge permits us to say the only conditions in which a hyperproteinemia and hyperglobulinemia are found with any degree of consistency are dehydration and multiple myeloma (Perlzweig, Delrue and Geschicker, ³³ Shirer, Duncan and Haden ³⁴). This latter observation made since Letterer's publication adds strong support to his contention.

DIAGNOSIS

If we may judge from the results of experimental amyloidosis in mice and the observations upon horses treated for the production of antisera amyloidosis is insidious, and does not make itself clinically manifest in man until the suppurative focus has been in existence for many months. According to Waldenstrom, ³⁵ it requires one to two years before the amyloid becomes deposited. Inasmuch as the spleen is the first organ and the one most consistently involved, enlargement of that organ is probably the first sign. As a rule, the clinician observes the patient when the disease has already spread to other viscera, especially the liver and the kidneys. Involvement of the liver never gives rise to gross evidences of hepatic insufficiency, but manifests itself clinically merely in enlargement of the organ. Sometimes the enlargement is extreme as in the case clinically reported by Rachmielowitz ³⁶ where it reached nearly to Poupart's ligament. The dominant clinical manifestations of generalized amyloidosis arise from involvement of the kidney, and indeed, most recent reports on the clinical

aspects of amyloidosis are concerned only with the renal manifestations under the title "amyloid nephrosis" We regard the term "nephrosis" as unfortunate for many reasons (1) Because under no circumstance is the amyloid kidney a pure epithelial involvement of the kidney according to the definition under which the term nephrosis was first coined, but always represents involvement of the connective tissue and vascular structures, (2) Because clinically the renal manifestations do not always correspond to the conventional criteria of nephrosis formulated by Epstein and others but are frequently accompanied by vascular reactions of which hypertension and azotemia are the prominent expressions, (3) Because in the light of modern studies, "nephrosis" is not a disease but a symptom complex whose clinical manifestations are the result of a hypoproteinemia from whatever cause The term nephrosis, therefore, if used at all should be applied to losses of protein sustained by way of the kidney

Albuminuria is the most constant symptom of generalized amyloidosis, it varies from a trace to many grams per liter As a rule albuminuria signifies involvement of the glomeruli by amyloid, but not necessarily so (Rosenblatt) On the other hand, amyloid infiltration of the kidney is not always accompanied by albuminuria When the albuminuria becomes excessive (more than 1 gram per liter) the typical secondary evidences of hypoproteinemia become manifest with anemia, edema, anasarca, cholesterinemia and doubly refractive lipoids in the urine (Rachmielowitz, Shapiro,³⁷ Noble and Major,³⁸ Bannick, Berkman and Beaver,³⁹ Rosenblatt¹⁵) Sometimes the cholesterol in the blood reaches excessive figures, in the case reported by Rachmielowitz, 625 mg per 100 c c of blood

In the majority of instances the systemic blood pressure in generalized amyloidosis is low Indeed Rosenblatt, in his large series, found no instance in which the pressure was over 140 mm of mercury On the other hand, hypertension has been observed by numerous observers (Vollhard and Fahr,⁴⁰ Bell,¹⁸ Noble and Major, Dixon) Sometimes the hypertension develops as a terminal event In the case reported by Gerber (reported previously during the lifetime of the individual by Rachmielowitz) the tension rose two and a half years after the first observation Perla and Gross report a similar observation in a patient 16 years of age The majority of observers associate hypertension with the onset of secondary renal contraction (Noble and Major)

Azotemia has been reported frequently In Dixon's series it was present in 26 per cent of the cases, it is apparently independent of the systemic blood pressure, even causing death with a normal or low tension (Bannick, Berkman and Beaver), thus differing from the usual association witnessed in the primary or secondary contracted kidney

A not infrequent symptom of amyloidosis is purpura It was present in one of my cases (Case 2) and has been reported by Königstein⁹ Perla and Gross,¹⁰ Leupold⁴¹ and Strauss⁴² Strauss reports amyloid involvement of the blood vessels of the skin in the purpuric areas

Since the introduction of the Congo red test (Bennhold ⁴³) the diagnosis of generalized amyloidosis has been placed on a sounder footing. This test depends upon the disappearance of the dye after intravenous injection of the dye. Melamed,⁴⁴ whose experience in Montefiore Hospital with the test has been extensive, regards the diagnosis of amyloidosis as justified when the retention of the dye is 50 per cent or over, doubtful when it is between 25 per cent and 50 per cent and negative when it is below 25 per cent. A retention of 100 per cent makes the diagnosis certain. Kramer and Som⁴⁵ found vital staining with intravenous Congo red of definite aid in outlining the borders of a localized amyloid tumor of the larynx. Gerber noted the persistence of the dye in the affected organs years after the Congo red test had been performed.

IS AMYLOIDOSIS REVERSIBLE?

This question is obviously important. Gardner⁴⁶ in 1891 reports the case of a man with extensive necrosis of the femur with all the constitutional evidences of amyloid disease: albuminuria, enlarged liver and cachexia. After amputation of the leg, the patient recovered completely. Walker⁴⁷ reports the case of a boy aged four, who two years after the onset of a chronic empyema developed albuminuria, enlarged liver and spleen and cachexia. A thoracoplasty was performed. One year later the liver and the spleen had diminished appreciably in size and the cachexia improved. Eight years later the boy was completely well. Waldenstrom,^{35, 48} in two publications, reports numerous biopsies of the liver upon suspected cases of amyloidosis and in three instances found complete disappearance of the amyloid after healing of a suppurative tuberculous focus. Incidentally he notes that a liver may not be enlarged and yet show considerable amyloid. Métraux⁴⁹ reports an extremely interesting observation. A child of 13 developed typical amyloid disease the result of a chronic osteomyelitis. The Congo red test was positive. The osteomyelitis healed, and five years later the Congo red test had become negative, the albuminuria had disappeared, and the liver had returned to normal size. Two years later the osteomyelitis recurred and three weeks later the patient died from sepsis. The liver showed amyloid with healing granulomatous changes, the Kupfer cells contained amyloid and the kidneys showed beginning contraction. It is doubtful whether the amyloid recurred after only three weeks' suppuration so that we must assume in Métraux's case the patient was clinically but not anatomically healed.

Recently Reimann⁵⁰ reports the case of a woman, aged 30, who developed amyloid disease two years after the first symptoms of tuberculosis and one year after a thoracoplasty. The Bennhold test showed complete disappearance of the dye after one hour. The patient slowly improved, and nine months later only a normal per cent of the dye was retained. All symptoms of amyloidosis eventually disappeared and three years later the

patient was perfectly well. The liver and the spleen were not palpable and the urine contained only a trace of albumin.

In experimental amyloidosis Kuczynski noted resorption of the amyloid if the lesion were not too advanced. Morgenstern also noted that amyloid deposits began to subside after stopping the injections of nutrose and at the end of four months had practically disappeared. In the liver he noted some connective tissue replacement. Grayzel, Jacoby and Warshall also noted resorption of amyloid in animals in the earliest stages of the process and especially if liver was added to the diet. No regression was noted in the advanced stages.

In summary one can conclude that the clinical regression of amyloidosis is possible provided the focus is removed. Whether complete anatomical healing with *restitutio ad integrum* is possible remains doubtful.

ATYPICAL AMYLOIDOSIS

This term was employed by Lubarsch to connote instances of amyloidosis in unusual sites and without apparent cause. There is usually no involvement of the liver and spleen, while such organs as the heart and lungs, the skin and striated muscles are particularly involved. Sometimes the amyloid occurs as tumor-like masses, either of pure amyloid or as a secondary involvement of a new growth (usually a myeloma). Frequently, the usual colorimetric reactions of amyloid are absent.

Lubarsch reported three cases. In the first, amyloid was deposited in the heart, lungs, stomach, esophagus, the intestines and the skin. In the second, the patient had signs of scleroderma and myotonia and a large tumor of the tongue which proved to be a massive deposit of amyloid. In the third, there was marked amyloidosis of the stomach, lungs, heart, spleen, trachea, the entire genital tract and the bronchial and mesenteric lymph nodes. Gerstel⁵¹ reports another case of huge amyloidosis of the tongue, with amyloid deposits in the skin of the neck, the gastrointestinal tract, the heart and the blood vessels. Pick⁷ reports two cases. The first, a man aged 54, had difficulty in swallowing and a generalized disturbance in muscular function. A diagnosis of myotonia, scleroderma and carcinoma of the tongue was made. Autopsy revealed a widespread amyloidosis of the muscles, the tongue, the heart, stomach, intestines, lungs and serous membranes. The second was a woman aged 51 with swelling of the tongue and muscles of the neck and thickening of the cervical skin. At autopsy there was found a diffuse amyloidosis of the tongue, the floor of the mouth, soft palate, pharynx, esophagus, stomach, intestines and diaphragm. In neither case was a cause discoverable. Recently Warren reports a case of general involvement of the musculature without involvement of the parenchymatous organs. Mollow and Lebell⁵² report the case of a man aged 60 who clinically showed hypertonia of the muscles, enlargement of the tongue, and abdominal pain. At autopsy generalized amyloidosis of the muscles and skin

was found, without involvement of the parenchymatous organs. Perla and Gross report three cases. The first was a female, 53 years of age, with extensive amyloid disease of the heart, tongue, gastrointestinal tract and other organs, who died of congestive heart failure. The second was a female aged 16 years, with extensive amyloid deposits in the kidneys, liver and suprarenals, who died in uremia. She had an ankylosis of one joint. The third case was a female, 63 years of age, with amyloid contracted kidneys who died in uremia. She had severe coronary sclerosis and a healed infarction of the left ventricle. The amyloid was limited to the kidneys. Strauss reports the case of a man, aged 72, who had dyspnea and generalized enlargement of the lymph nodes. The amyloid was found in the epi- and pericardium, lungs, lymph nodes, adipose tissue. There was a massive involvement of the muscle-free blood vessels. He discusses 28 previously reported cases of atypical amyloidosis and suggests the name para-amyloidosis to comprise these bizarre forms.

Herxheimer and Reinhart⁵³ collected 38 cases of amyloidosis of the upper respiratory tract and lung and eight cases of amyloidosis of the lung. They hold that no sharp distinction can be made between the generalized and localized forms of amyloidosis, because one may find the most extraordinary combinations.

In the atypical variety may be mentioned the tumor-like masses found in the upper respiratory tract cited by Pollak⁵⁴ and Kramer and Som.

Lubarsch has attempted to classify these atypical cases of amyloid disease into three groups: (1) Those involving mainly the skin simulating scleroderma, (2) Those in which the dominant infiltration is in the muscle simulating myotonia, (3) Those involving the tongue simulating neoplasm. In addition we would add a fourth, namely, cases of amyloidosis associated with chronic deforming arthritis. This seems the best clinical classification of so-called atypical amyloidosis at present at our disposal, but it is by no means to be considered inclusive.

SUMMARY

The chemical nature of the amyloid substance is not conclusively known. Pathologically, amyloidosis usually represents an involvement of the reticulo-endothelial system and the pericapillary and periglandular connective tissue. Almost any tissue except the cerebrospinal substance may be involved, with a special predilection for the muscles and skin. In addition to the conventionally known causes, such as tuberculosis, chronic suppuration, syphilis, Hodgkin's disease and necrotizing blastomata, amyloidosis, either general or localized, is frequently associated with multiple myeloma and its attendant Bence-Jones proteinuria and with ulcerative lesions of the bowels. A case of amyloidosis associated with chronic deforming arthritis is reported. Such an association has been reported not infrequently, though the relationship is not clear. The number of reported cases of amyloidosis

without apparent cause, in other words, primary amyloidosis, is progressively increasing and constitutes an important nosological entity. Experimentally, amyloidosis has been produced in various ways, but the underlying principle represents a prolonged overdosage with protein, preferably by the parenteral route. The evidences in favor of Letterer's contention that amyloidosis is the result of a hyperproteinemia and an associated hyperglobulinemia are reviewed and may be regarded as highly suggestive.

The clinical diagnosis of amyloidosis is dependent upon the following signs: (1) The enlargement of the viscera that may become palpable, namely the spleen and the liver. (2) The development of signs of the so-called nephrotic, but better termed hypoproteinemic syndrome consequent upon the involvement of the kidney. These are proteinuria, diminished blood proteins, hypercholesterinemia and generalized anasarca. In later stages, general arterial hypertension and azotemia may develop. The latter may occur without a co-existing hypertension, in contradistinction to other varieties of renal disease associated with hypertension. (3) Purpura of the skin. This sign has been less commonly observed but has been reported sufficiently frequently to be regarded as a symptom of the disease. (4) The Bannhoid Congo red test forms the most important confirmatory test of amyloidosis. A 100 per cent retention of the dye is diagnostic.

There is abundant evidence that amyloidosis is clinically reversible, whether it is anatomically reversible has as yet not been definitely proved. Atypical amyloidosis constitutes a diverse variety of anatomical lesions. Clinically they may thus far be classified into four groups: (1) cases simulating scleroderma, (2) cases simulating myotonia, (3) cases simulating tumor of the tongue, (4) those associated with deforming arthritis.

ADEQUATE TESTS OF CURATIVE THERAPY IN MAN

By W D SUTLIFF, M D , *Chicago, Illinois*

It is widely recognized that the subject of therapeutics has a great emotional appeal for the layman, and as a corrective measure a clear view of therapeutic possibilities is expected of the physician. But it is on the subject of therapy that the demands of practice strain the exercise of cool judgment to the utmost. The doctor may adopt either an exaggerated skepticism, or an exaggerated optimism, depending on his temperament. He is also nearly always subject to fashions in the use of certain popular methods of treatment. Due to such influences, no doubt, the element of belief as distinguished from objective data plays a large part in determining the physician's attitude toward therapeutic problems. A question that is often asked when therapeutic practice is discussed illustrates this dependence on belief. One physician asks another "Would you demand such treatment for yourself in case you were ill?" This question implies a consideration of the safety and freedom from discomfort of the therapy, but its main object is obviously to pierce beyond any facts and find the state of belief of the person who is quizzed. The profession is thus quite practical but not entirely rational when questions of therapeutic efficiency are concerned. This irrational approach persists today in spite of the fact that it has been repeatedly shown that it is possible to measure the effectiveness of curative therapy. In this paper the data accumulated in support of the value of several well known curative agents are reviewed and the experiments are cited as examples of effective methods for testing therapeutic agents. Such a discussion is not to be found in the recent medical literature. It is hoped that it will aid in defining standards of achievement for those who advocate new cures, and also contribute to a better reasoned attitude by the profession when they are confronted with reports of therapeutic success.

During the introduction of quinine, of diphtheria antitoxin, and of insulin, testing methods ranging from the most primitive to the most exact were devised and used. The experiences with these three medicaments furnish good examples of the various types of clinical therapeutic experiments that have proved most useful.

The possibility of curative therapy specific for a given disease was first demonstrated satisfactorily in the case of quinine¹ introduced to Europe in 1638. It was introduced in the form of various preparations of Peruvian Bark, in the same way that many other products of vegetable origin were made known to the medical profession in the seventeenth century. Reports of single cases or "cures" that resemble testimonials were recorded. The

* Received for publication January 13, 1936

From the Department of Medicine and the Douglas Smith Foundation for Medical Research, University of Chicago

"cures" seem to have derived much of their importance as a result of the rank of the persons treated, for example, it is related that a provincial governor of Coreggidor was successfully treated later the Countess of Chin Chon, and finally in 1649 the future Louis XIV of France. The Jesuits adopted the bark and distributed it widely. It was also sold by drug dealers. Because there was little curiosity in Europe as to its source, and because the Indians who gathered it for market did not believe that it had any potency as a medicine, a good deal of adulteration and substitution occurred.

Opinion was divided as to its value for thirty to forty years. During this time and also later, the preparations of the drug frequently lacked potency. Certain prejudices of the time such as those resulting from the prevailing theories of disease processes, and from the religious character of some of the drug's supporters (as the Jesuits) prevented an impartial judgment. In 1676, Sydenham gave an account of the use of Peruvian Bark that was of a different character.² He related his observations on the use of the Bark over a period of years. He described the type of fever, namely the remittent fever, in which it was useful, the symptomatic results, and by considering dosage explained the tendency to relapse observed by others. The dosage that he recommended was quite similar to that in use today. This publication no doubt had some direct effect upon the adoption of the drug, but it was not as influential as the activities of Talbot who popularized its use as part of a secret formula which was published after his death by Louis XIV. The disclosure that Peruvian Bark formed the potent part of this formula apparently fixed its value until the present time. Much has since been learned about Peruvian Bark. The active principle was isolated in 1821, and the parasite of malaria was recognized by Laveran in 1880, but these and other facts of lesser importance have not materially altered our views in regard to its therapeutic application.

The vicissitudes of quinine from the time it was first called to the attention of Europeans until it was finally accepted are duplicated in many respects in therapeutic efforts today. Remedies are sometimes used and advocated by lay persons, medical sects, and by physicians, in the treatment of ill-defined groups of diseases, with no rational explanation of the results expected. Data may be presented in support of such claims that have no more value than a testimonial. The customary reaction to such claims is the setting up of a group that believes, and a group that does not believe, and these cannot reconcile their differences until impartial experiment determines the truth so it can be seen by all.

Sydenham's contribution to the methods of observing therapy was of the greatest importance. He showed that a skillful clinician with a knowledge of the course of a given disease, derived from experience, could observe the effects of medication and come to a valid conclusion as to its worth. This method is within the daily activity of every active and skillful clinician. It has been used more widely than any other, but the results have often been unsatisfactory. It is almost impossible to draw the boundary line between

skillful observation and the unconsciously colored reports of those who favor belief or disbelief. The personal integrity and skill of the individual author cannot be known to all of us, and without this knowledge reports of observations of symptoms as serially observed in practice cannot be evaluated. As a result, and due to the combined efforts of a long succession of physicians, improved ways of testing medicaments have been devised.

The development of further specifics such as diphtheria antitoxin dominated medical thought and progress during the isolation of many bacterial agents and the beginning of immunology in the late nineteenth and early twentieth century. The infectious theory of disease was leading to active search for curative methods in a fruitful direction. Experimental medicine was active and productive.

The steps through which diphtheria antitoxin came to the attention of the profession were as follows.³ Löffler in his description of the diphtheria bacillus noted that although it did not invade the body it produced general systemic and distant toxic effects. Roux and Yersin in 1889 showed the presence of a soluble toxin by inoculating animals with broth from which the bacterial bodies had been separated by means of porcelain filters. Von Behring, Wernicke and Futaki showed that the blood serum of inoculated animals and those recovering from the disease neutralized the effect of such toxins when passively administered in other animals. In the years 1890, 1891 and 1892 these authors described the production of such antibodies in horses, sheep and cattle, and gave methods of estimating their potency in guinea pigs. During the course of these studies, the application of this knowledge of antibodies to the cure of disease in man was kept in mind, and at Christmas time in 1891, the first child was given 50 c.c. of sheep antitoxic serum subcutaneously in the von Bergmann Clinic with a satisfactory result as reported by von Behring and Wernicke. More extensive clinical trials were made in 1892 and 1893, and the antitoxin was supplied to others and widely used after 1894.

No therapeutic measure so well tested in animals had ever before been given to clinicians for use in patients, and the lesson of the worth of carefully controlled observations led to a conscious effort to conduct clinical tests in a similar manner. Symptomatic results from antitoxin sufficiently striking to form the basis of a report like Sydenham's report on Peruvian Bark, were apparent when only a few patients had been observed. The membrane was found almost invariably to cease spreading, and to disappear, together with general improvement. The number of cases treated and described in written reports was enormous. Two new features of these reports are noted. (1) The adoption of simple statistical methods such as averages, tables and graphs to describe the effect of therapy on symptoms, on the incidence of complications and on the death rate. (2) The comparison, wherever possible, of these findings with those of control series of cases. It was widely felt that observations on large numbers of cases were better than observations on small numbers of cases because the variability of

the disease was a relatively smaller source of error in the larger series. As control series for comparison, nearly all workers used groups of patients seen in the years immediately before 1894, the year in which the general use of diphtheria antitoxin was begun.

It seemed to many that these data gathered on this unprecedented scale, and according to methods that were new in part, did not constitute an improvement over the simpler and easier studies of Sydenham. A good many criticisms were made.⁴ Most of these were concerned with the suitability of the controls seen previous to 1894 with which treated cases were compared. It was pointed out that all the cases reported were seen in hospitals, and that the character of the hospitalized cases might conceivably change from time to time due to variations in the criteria for hospitalization. Further studies outside the hospitals disposed of this objection. It was further pointed out that the treated series were diagnosed by means of throat culture, but that control cases were not so diagnosed. Analyses showed that only very small errors could arise from this source. A more serious objection to the use of controls observed before 1894 was raised by epidemiological studies. Within a few years before or after 1894 a severe world wide epidemic of diphtheria came to an end, without any relationship to the introduction of antitoxin as a therapeutic agent. The number of cases fell off rapidly, and the proportion of fatalities among the remaining cases also became less. A false idea of the effectiveness of the serum therapy had thus been gained from comparisons between cases seen before and after the termination of this epidemic. The great importance of studies in which the control observations were adequate was then acknowledged. In the best of these, by Fibiger, in Blegdam's Hospital two groups of patients were observed simultaneously in the same hospital, and chosen by means of numbers assigned impartially on entrance. In two other experiments the results of treatment were compared in two similar, but separate hospitals at the same time, in the same city, in Berlin at the Charité and the Bethanien Hospitals, and in Paris by Roux, Martin and Chaillou. Since such statistical studies of death rates are the material that is now quoted in support of this important medication, a table is given which indicates the results of several representative experiments, the first with the inadequate controls, the other three those just described.

TABLE I

Mortality Rate of Diphtheria Cases Treated with Antitoxin Compared with Cases Treated without Antitoxin

Reference	With Antitoxin			Without Antitoxin		
	Number	Number Died	Per cent Died	Number	Number Died	Per cent Died
New York ⁵	56,425	8,464	15.0	27,210	8,496	34.9
Paris ⁶	448	11	24.5	520	312	60.0
Berlin ⁷	317	53	16.7	260	102	43.1
Copenhagen ⁸	239	8	3.5	245	31	12.5

The initial venture of modern medicine into therapeutics was thus accomplished in a scientific manner. The actions and potency of diphtheria antitoxin were first carefully ascertained in animals. From these experiments the dosage of the antitoxin was easily controlled. The observation of the action of antitoxin in a consecutive series of cases according to the simple technic that Sydenham employed played a large part in its wide adoption. For written reports, however, statistical methods came into play. These gave results that were much too favorable, due to the fact that epidemic fluctuations were not observed, but the three experiments quoted above appear to have been adequately controlled. The data quoted in the above table have withstood the criticism of several critical generations.

As other therapeutic sera have been developed the same methods have been used to ascertain their usefulness in man. New variations in the application of the statistical method were often required. Antimeningococcic serum was used on a large scale first in the epidemic of 1911, and 1912, with a mortality rate (30.9 per cent) much below that always previously reported (50 per cent to 80 per cent).⁹ Since that time results have been found satisfactory by many, especially by those who have paid particular attention to the use of serum possessing the necessary type specific antibodies (Wadsworth, mortality rate 17.8 per cent).¹⁰ Dissatisfaction has been reported repeatedly by physicians who happened to see some marked variation from the average death rate in a small experience or by physicians who observed an epidemic in which the serum was not effective. It is unfortunate that no well selected series of control cases was compared with those treated with serum, as McCoy,¹¹ and more recently, Petrie¹² have pointed out. Those who have had definitely unfavorable experiences have possibly been given greater importance than they deserved. Petrie outlines the control methods that would be required for collecting the best data as follows: (1) A group of patients treated with serum. (2) A group of patients treated with frequent lumbar spinal drainage and (3) A group of patients treated intraspinally with normal non-immune horse serum. (4) A group of patients treated expectantly.

The serum treatment of lobar pneumonia may be divided into two periods in regard to the methods of testing employed. Before 1904 antipneumococcic sera were prepared without respect to the serologic differentiation among the pneumococci, and were used in small groups of cases by a large number of practitioners. The results were collected¹³ and the total was reported in statistical tables, together with each author's descriptions of the symptomatic results but with no thought of controls. The reports were favorable, but were not taken seriously, and as commonly happens with therapeutic procedures that are not definitely proved to be effective, the procedure fell into disuse, without the production of any evidence that could be shown to be unfavorable. Type specific antipneumococcic serum was shown to be clinically useful first by Cole,¹⁴ who observed a series of patients accurately after the method of Sydenham and, due to the known excellent

character of his ability and experience, these results were accepted by many, despite the lack of adequate controls. Others,^{15, 16, 17, 18} have made great efforts to compare treated patients with controls in the same hospital during the same season. In one instance¹⁹ a direct comparison was undertaken between non-specific and specific horse serum concentrates. These results, expressed by means of tables of figures, are probably the most extensive and clear of any such therapeutic investigations.

In the case of scarlet fever antitoxin the symptomatic effects were observed repeatedly^{20, 21} and were compared with adequate controls, but the naturally low death and complication rates prevented the collection of the best kind of comparable data as to its therapeutic efficiency. A further clinical experiment was conducted by Blake and Task²² that deserves special comment from the point of view of the methods of investigation employed. The clear rationale that had been provided for the use and actions of scarlet fever streptococcic antitoxin by means of the Schultz Charlton test and Dick test led Blake to inquire not only "Does the serum cure the disease?", but "Does the serum neutralize the toxin that is present and simultaneously cure the disease?" He was able to show by doing skin and neutralization tests with the sera taken at different stages of scarlet fever from 133 patients that toxin circulated in the blood stream during the time of greatest toxicity, that the toxic action of such blood was prevented by the administration of antitoxin, and that the neutralization of the toxic action of the patient's serum was followed by clinical cure of the disease. This method is applicable only where something of the action of the medicament is understood, and some essential feature of the disease can be made the object of measurement. Claude Bernard²³ early contrasted such rational experimental study of therapy in man and animals with statistical methods, presenting an array of objections to observations that were applicable to the mystical "average case." Therapeutic investigations in man such as Claude Bernard urged became of importance as the knowledge of physiology accumulated.

The most important developments in therapeutics in the recent past have been in the field of physiology as applied to medicine, by the replacement of hormones and vitamins lacking in disease. Insulin was the first of these. The methods through which its use became established are typical²⁴.

A large number of workers had confirmed and accepted Minkowski's explanation that the pancreas elaborated a hormone necessary to the metabolism of glucose. Diabetes was reproduced in the dog and carefully compared with diabetes in man. The disturbance in carbohydrate metabolism was measured by means of urinary and blood sugar, and the respiratory quotient. The discovery of Banting and Best, that watery extract of the pancreas maintained depancreatized dogs and lowered the blood sugar of rabbits, was the culmination of an extensive series of experiments by others which indicated that such a substance was present. Its application to man was a foregone conclusion. The preparation of extracts sufficiently non-toxic to be safe proved a temporary stumbling block, but this difficulty was

solved with the aid of Collip. Once a suitable concentration of the material was obtained and administered, observations of the carbohydrate metabolism showed that profound changes had been secured. Confirmation of these findings by others was all that was required to make obvious the effectiveness of the medicament. Subsequent analyses of series of such treated cases have been made with the purpose of clinical description and only incidentally to confirm the fact apparent to all that insulin is a specific remedy for diabetes mellitus. Such methods mark a definite step forward because the demonstration is conclusive and the information is not statistical. It is applicable to individual cases instead of the average case. The basis upon which such data may be developed is a clear conception of the nature of the disease.

When this search for trustworthy methods of testing therapeutic efficiency was begun it was hoped that experiments could be classified into various kinds. This has been done. Three different types of testing methods were distinguished as follows:

1. Observation of consecutive cases and comparison with the fund of experience (Sydenham)

2. Counting of cases, preparation of statistics, and comparison with similarly prepared controls (Louis)

3. Observation of the effect of medication upon some of the essential features of disease (Claude Bernard)

Outstanding successful examples of the application of each of these methods are described above. It was also hoped originally that the usefulness of each of these methods could be determined objectively from the reports in the literature. A tabulation was projected to show the results of different methods applied to the same therapeutic measure, in which only subjects about which general agreement had been obtained were to be included, with attention to the successful demonstration of the absence of effect as well as the presence of effect. Such comparisons were found to be impractical because the data were not adequate. There was a tendency for only one method to be used for each therapeutic agent, and carefully prepared reports of the lack of effect of therapeutic agents were very rare.

The statistical method is the only one of these three methods that has been the object of frequent discussion from the point of view of methodology. There are those who regard the statistical method, so called, most highly. There are others who place very little reliance upon information obtained in this way. The method in principle as Louis stated it²⁵ is quite simple. "For true experiences in medicine as I have elsewhere remarked (and as anyone may be convinced by what has preceded), true experience in medicine can result only from the exact analysis of numerous parts, well ascertained, classed according to their resemblance, compared with care, and counted." The mathematical manipulations that are useful in therapeutic experiments are of the easiest, and mistakes are rarely attributable to faulty statistical methods. Disappointing results have been obtained most often

either by investigators who have collected larger numbers of observations that were uncritically made, or by those who have not taken the trouble to secure comparable controls. The setting up of adequate controls is probably the chief technical difficulty. Experimentation on such a scale with the illnesses of people is often frowned upon. It is also the common experience that a small number of favorable results leads many of the more optimistic practical physicians to question whether it is ethical to withhold the therapy from enough impartially selected patients to provide adequate controls. The use of statistical data for judging therapeutic efficiency might become infrequent due to such complexities in its use were it not indispensable in certain situations. When the rationale of a measure is not well enough understood to provide objective evidence of cure in a single case, statistics are the only resource. Even where a thoroughly rational method of observation of the effects of therapy is known, additional information of importance such as the general death rate, complication rate and relapse rate, may be determined by means of statistics.

The classification of therapeutic testing methods used above is not exhaustive. It is obvious that the skillful use of such methods depends upon the alteration and adaptation of the technic to suit each individual disease and therapy. The value of this discussion is thought to lie in pointing out the possibility and emphasizing the desirability of careful, conclusive trials of therapeutic measures in man.

CASE REPORTS

SPONTANEOUS SUBARACHNOID HEMORRHAGES AND THEIR RELATIONS TO RUPTURES OF SMALL ANEURYSMS IN OR NEAR THE CIRCLE OF WILLIS

By LEWELLYS F BARKER, M D , F A C P , *Baltimore, Maryland*

DURING recent years the accurate clinical diagnosis of the nature and localization of intracranial vascular accidents has been greatly advanced, thanks to more careful clinical pathological studies on the one hand, and to the application of the methods of cerebral angiography through the injection of thorotrast or other contrast substances, on the other. In particular, the hemorrhages into the subarachnoid space in the region of the circle of Willis with filling of the cisterna can now be usually recognized with certainty and appropriate treatment can be instituted early. The case reported here illustrates well the symptomatology and the results of prompt treatment in a case of sudden subarachnoid hemorrhage.

CASE REPORT

The patient, Beneditto M, white, 52 years of age, a contractor, was admitted to the Osler Clinic (service of Professor Warfield T Longcope) on the evening of February 1, 1936, with the complaint of severe headache that had started suddenly four days earlier in the occipital region and had gradually become more generalized and more severe.

Family History The parents of the patient are both dead, the mother having died at the age of 62. He was one of a family of six, four of whom are living and well, one having died of influenza at the age of 15. The family in general has been healthy except for a tendency to obesity. There has been no history of any disease similar to the patient's in his family.

Past History of Patient Except for measles in childhood and an attack of pneumonoma at the age of 12, the patient has enjoyed excellent health except that for many years he has had a monthly headache lasting 10 or 12 hours, apparently migraine. He denies venereal infection at any time in his life.

His habits with regard to food and drink have been abnormal. It is said that he has taken only one meal a day (in the evening). On rising in the morning he has taken one cup of coffee with two small glasses of whiskey. There has been no mid-day meal. He has been a liberal drinker of wine, consuming six or seven bottles daily in the summer time and often as many as 10 bottles daily in the winter time. In addition, he states that he has taken "as much beer as he could get." He smokes from three to six cigars daily.

He has never been operated upon and has suffered no traumata.

About one year ago his eye-sight began to fail and he was fitted with glasses.

* Received for publication March 28, 1936 (Thursday Clinic to Senior Students of the Johns Hopkins Medical School, February 13, 1936)

History of Present Illness Four days before admission to the hospital, the patient, having felt perfectly well until that time, had spent the afternoon at the movies. After supper, the one meal that he eats each day, he had not felt quite up to the mark. About 8 00 p.m. he went from the hot kitchen upstairs to a cool porch to get some clothing and on returning to the warm room he was suddenly seized with a severe, continuous, throbbing headache, beginning in the posterior part of the head and right temporal region and soon spreading over the whole of the head. He went to bed immediately, felt nauseated and tried to vomit within ten minutes after the onset of the headache. He slept some through the night but next day the headache was worse. He felt feverish, sweated profusely and found it difficult to open his eyes or to see what was going on about him and was unable to eat as food caused nausea. He could, however, retain water in the stomach. On the second day, he took 12 pills that came from a drug-store but without any relief. Indeed, the symptoms not only persisted but became intensified. There was no bowel movement during four days despite numerous doses of salts. He was not unconscious or stuporous at any time and remembers coming to the hospital. There is no history of overexertion, excitement or trauma preceding the attack.

Physical Examination (Dr. Murrick and Dr. Harvey) Temperature 101°. Respiratory rate 28. Pulse rate 56. The blood pressure was 150 systolic, 75 diastolic. The patient was evidently suffering severe pain and was so acutely ill that he was disturbed as little as possible during the examination. There was evident photophobia. The patient was somewhat obese and the skin was moist. The pupils were small and reacted well, both to light and on accommodation. There was no nystagmus and no conjugate deviation of the eyes. Examination of the eye grounds was negative. There was some deflection of the nasal septum to the right. Moderate gingivitis. Slight pharyngitis. The glands at the angle of the jaw were palpable but the glands elsewhere were not enlarged. No enlargement of the thyroid gland. There was marked rigidity of the neck and a definitely positive Kernig sign. The lungs and heart were negative. The radial arteries were palpable but not much thickened. Abdomen and genitalia negative. Deep reflexes everywhere normal. Abdominal and cremaster reflexes present. Babinski negative on both sides. There was some tenderness on pressure over all of the anterior part of the head.

Laboratory Tests Blood: red blood cells 5,330,000, hemoglobin 120, white blood cells 13,860, polymorphonuclear neutrophils 80 per cent, eosinophils 2 per cent, small mononuclears 18 per cent. Urine: Sp. gr. 1.020, trace of albumin, no sugar, a single hyaline cast seen, no white blood cells, no red blood cells. *Cerebrospinal Fluid* Lumbar puncture done in the accident room before sending the patient up to the ward revealed a cerebrospinal fluid that was under pressure of 230 mm of water. It was grossly bloody, contained 140,000 red blood cells per cu. mm. and 520 white blood cells of which 80 per cent were polymorphonuclears and 20 per cent small mononuclears. On sedimentation the supernatant fluid was yellowish (xanthochromia).

Course in the Hospital The patient was kept quiet in bed with orders for liquid diet, with limitation of the fluids to 3,000 c.c. He was given paraldehyde occasionally in 20 c.c. doses.

On the following day, February 2, the blood pressure had fallen to 144 systolic and 80 diastolic but the patient still complained of severe pains in the head. In the afternoon he was given a dose of avertin and the blood pressure afterwards fell to 130 systolic and 60 diastolic. Another lumbar puncture was done, the pressure was 210 mm., Queckenstedt negative. Red cell count in the spinal fluid 130,000. White cell count 600. That evening the patient felt much better though he was still drowsy from the sedatives. The headache had become less severe.

On February 3, another lumbar puncture was done. The fluid was blood tinged. About 8 c.c. were withdrawn. The pressure was 240 mm., Queckenstedt negative.

Red blood cells 21,000 White blood cells 420 The headache continued but was not quite so severe He was given another dose of avertin

On February 4, the patient complained of frontal headache There was no vomiting nor any significant change in respiration, blood pressure or pulse Cerebrospinal fluid (8 c c) removed at 8 00 a m showed an initial pressure of 210 mm The fluid was cloudy and of pinkish color Red blood cells 14,420, white blood cells 230

Another lumbar puncture was done at 8 00 p m The initial pressure was 220 mm About 18 c c of pinkish, slightly cloudy fluid were removed Red cell count 12,000

On February 5, lumbar puncture was done in the early morning The initial pressure was 190 mm, 7 c c of pale pinkish fluid removed red blood cells 9,700 During the day the patient improved much symptomatically The blood pressure was 140 systolic and 90 diastolic The respiratory rate 20 Pulse rate 68 He received no sedatives during that day except a little codeine At 9 00 p m another lumbar puncture was done The initial pressure was 190 mm, 10 c c of pale yellowish fluid removed The red cell count was 13,000 in the fluid

On February 6, in the afternoon, another lumbar puncture was done The initial pressure of the fluid was 60 mm, 8 c c of pale yellowish fluid removed Red cell count 130, white cell count 120

By February 7, the patient had improved so much that he said he felt himself again The headache had disappeared, he could open his eyes comfortably, the neck was no longer stiff, and the Kernig sign had disappeared Cultures from the blood and cerebrospinal fluid remained negative

Diagnosis In this case there would seem to be but little difficulty in arriving at the following diagnosis

- 1 Spontaneous subarachnoid hemorrhage, probably arising from rupture of a small aneurysm in or near the circle of Willis
- 2 Migraine
- 3 Obesity
- 4 Presbyopia
- 5 Faulty habits
 - (a) Inadequate diet,
 - (b) Potatorium

In the absence of any history of trauma, of chronic arterial hypertension, and of symptoms suggestive of brain tumor, hemorrhage into the subarachnoid space due (1) to injury of the skull and meninges from an accident, (2) to bleeding in a tumor with escape into the subarachnoid space and (3) to intracerebral apoplexy with passage of blood into the ventricles or subarachnoid space could be easily ruled out so that the diagnosis of so-called spontaneous subarachnoid hemorrhage had to be made Moreover, the sudden onset, with severe headache, nausea and rigidity of the neck indicative of meningeal irritation were strongly suggestive, and the cerebrospinal fluid on lumbar puncture confirmed the diagnosis

The fact that the patient suffered from migraine (monthly attacks) is of some interest, since some authors (especially Goldflam) have emphasized the possibility of subarachnoid hemorrhage of vasoneurotic origin, a point that I shall refer to later

INCIDENCE OF SPONTANEOUS SUBARACHNOID HEMORRHAGE

The frequency of occurrence of so-called spontaneous subarachnoid hemorrhage has only recently begun to be realized Though the condition was described as long ago as 1886 by Bramwell, it is only in recent years that the symptomatology has been studied carefully enough to permit of the recognition

of a characteristic syndrome that permits of diagnosis during life and the institution of helpful treatment promptly. Even today, many cases, especially those of milder type, are almost certainly overlooked, recovery in such milder cases by natural processes is the rule.

ETIOLOGY AND PATHOGENESIS OF SPONTANEOUS SUBARACHNOID HEMORRHAGE

Hemorrhage into the subarachnoid space due to traumatic laceration of the meninges, to hemorrhage into neoplasms that rupture to the surface, and hemorrhage because of diapedesis in blood dyscrasias are not included under the term spontaneous subarachnoid hemorrhage, in the latter the extravasation of blood into the subarachnoid space is due to spontaneous rupture of a blood vessel. As to the cause of such spontaneous rupture there has, through the years, been much discussion. Formerly, syphilis was thought to be an important cause but this idea has been shown to be erroneous, though in very rare instances syphilis may be the cause of a spontaneous subarachnoid hemorrhage it certainly cannot be a common cause.

In older patients, arteriosclerosis with chronic arterial hypertension has been thought of as the cause and in some cases this explanation has been found to be correct.

Another idea that has been promulgated is that some spontaneous subarachnoid hemorrhages may depend upon vasoneurotic influences. Thus Goldflam has suggested that the hemorrhage may be due to a functional disturbance of vasomotor control similar to what is seen in migraine, Raynaud's disease, and erythromelalgia, after abnormal vasoconstriction active hyperemia takes place and capillary oozing in the subarachnoid space results. Goldflam stated that in five of his 13 cases of subarachnoid hemorrhage the patients suffered from true migraine. It is interesting that the patient reported in the clinic today has also suffered from migraine throughout his life. A study of the bibliography of subarachnoid hemorrhage shows, however, that migraine is relatively rare in association with such hemorrhage and Goldflam's hypothesis seems to me to be untenable.

Though spontaneous subarachnoid hemorrhage may occur at any age, it is most common in young adults and is quite common in children. In recent years the idea that such subarachnoid hemorrhage depends in the main upon a primary weakness of the muscular coat of the arteries has gained ground, the very frequent association of subarachnoid hemorrhage with small aneurysms in the arteries at the base of the brain at the junction of a larger artery with a smaller branch strongly corroborates this view.

As early as 1859, Sir William Gull pointed out that small intracranial aneurysms were much more common than was usually thought and were often overlooked at autopsy since the sac is often small, thin and transparent, and the changes following rupture may easily obscure the little sac. At that time he said that whenever young persons die with symptoms of ingravescent apoplexy and after death a large effusion of blood is found, especially in the meshes of the pia mater, the presence of an aneurysm is probable.

The careful studies of C. P. Symonds (1924) also favored unrecognized aneurysm of congenital origin as the probable cause of obscure cases of subarachnoid hemorrhage.

Thanks to the exhaustive studies of Dr. Wiley D. Forbus, formerly of our department of pathology here, the origin of intracranial aneurysms of the superficial

cerebral arteries seems definitely to have been found. In a negro who died at the age of 24 with typical symptoms of spontaneous subarachnoid hemorrhage he found five small saccular aneurysms involving the left middle cerebral and the right and left anterior cerebral arteries and there had been rupture of the aneurysm of the right anterior cerebral artery into the subarachnoid space. After careful gross and microscopic studies he found that the aneurysms arose only from vessels belonging to the carotid system, that they were all located at points of bifurcation of the vessels, that there was a total absence of evidence of acute or chronic inflammation in connection with the aneurysm, that there was a definite defect in the muscular coat at numerous points of division in the right and left middle cerebral arteries, and that the location of aneurysms corresponded exactly to the location of muscular defect in the wall.

Such defects in the muscularis seem to date from embryonic life. They give rise to focal weakness in the vessel wall and may be followed by degeneration of the internal elastic membrane due to continued overstretching of that membrane, after which aneurysm can develop. Though Tuthill has attempted to refute these findings of Forbus, the majority of clinicians and pathologists interested in the subject are inclined to give full credence to the views expressed by this investigator. It is interesting that the most frequent defects in the muscularis in the arteries in the circle of Willis are at the point of junction with some branch or bifurcation, just the point at which the pressure in the blood vessel is maximal.

THE CHARACTERISTIC SYMPTOMATOLOGY OF SPONTANEOUS SUBARACHNOID HEMORRHAGE

When a subarachnoid hemorrhage is not too large or profuse, it is followed by a series of symptoms and signs that are very characteristic and make the diagnosis certain. These may be summarized as follows:

1. A sudden onset, often with a feeling as though something had "snapped" in the head and followed by severe occipital pain which later tends to become generalized.

2. Nausea or vomiting almost immediately after onset.

3. Within a few hours marked rigidity of the muscles of the neck with positive Kernig and Brudzinski signs.

4. On cautious lumbar puncture, blood will be found evenly distributed throughout the fluid in each of three successive tubes.

If these four symptoms and signs are found, the diagnosis is very easy.

When the subarachnoid hemorrhage is greater, mental confusion, agitation or even coma, may quickly follow the onset, and with very large hemorrhages there may be compression of the medulla oblongata with disturbance of respiration, marked bradycardia, and marked rise in blood pressure.

Death sometimes occurs very quickly in large hemorrhages, but if death does not occur the larger hemorrhage will be followed by bradycardia, photophobia, often choking of the optic discs, sometimes nystagmus and anisocoria, and sometimes pyramidal tract symptoms with positive Babinski sign.

Within a few hours after a subarachnoid hemorrhage the temperature begins to rise and slight fever continues for a time accompanied by polymorphonuclear leukocytosis. If later lumbar punctures are carefully done and the red cells are

allowed to sediment the clear supernatant fluid shows a definite yellow tinge (xanthochromia). The cerebrospinal fluid shows a greater number of white blood corpuscles than would correspond to the amount of blood present, indicating some inflammatory reaction on the part of the meninges. These findings in the cerebrospinal fluid in subarachnoid hemorrhage were so well described by From that but little has been added since he made his studies.

Attempts have been made to differentiate between subarachnoid hemorrhage from the anterior group of vessels (internal carotid, middle cerebral and anterior communicating arteries) and hemorrhages occurring in the posterior group (posterior communicating arteries, posterior cerebrals, basilar artery, vertebral artery). In the former, pain in the ophthalmic division of the nervus trigeminus is prone to develop, along with weakness or paralysis of the eye muscles and sometimes with exophthalmos. In hemorrhage from the posterior group, one sometimes sees hemiplegia or paraplegia, dysarthria, dysphasia, or mild cerebellar symptoms, particularly when the basilar artery bleeds.

The small aneurysms that most often give rise to these subarachnoid hemorrhages are rarely large enough to produce symptoms before hemorrhage takes place. If they should be large enough, the symptoms are as a rule neighborhood symptoms due to mechanical pressure.

TREATMENT OF SPONTANEOUS SUBARACHNOID HEMORRHAGE

If the patient is seen within 24 hours after the onset of the first symptoms (severe pain in the head, nausea and vomiting, and stiffness of the neck), the question of lumbar puncture for examination of the cerebrospinal fluid at once arises for it is desirable to decide as early as possible whether a meningitis is present or whether we have to deal with intracranial hemorrhage (either subarachnoid or intracerebral). If there be subarachnoid hemorrhage there is always some danger in making a lumbar puncture during the first 24 hours, but if it be very cautiously done a little fluid sufficient for the making of the differential diagnosis can be withdrawn without danger. If the fluid is bloody in three separate portions we can be sure of subarachnoid hemorrhage. In milder cases one will be satisfied with this for the moment, keeping the patient at rest in bed with the head elevated and administering sedatives for the pain. If the blood pressure be high, the withdrawal of from 300 to 500 c c of blood from a vein at the bend of the elbow would be indicated.

In severe cases in which a comatose condition develops quickly after onset or in which there are symptoms of compression of the medulla or pons indicating a larger outflow of blood, it may be necessary either to withdraw more fluid by the lumbar route or, perhaps better, by means of cisternal puncture as a life-saving measure, being cautious, however, not to reduce the pressure to below half the initial figure. In a few cases of severe hemorrhage, surgeons have ligated one internal carotid artery.

After the first 24 hours, cautious lumbar puncture may be done once or twice in the 24 hours with removal of relatively small amounts (3 to 5 c c) of fluid, for the relief of the pain in the head and to help in drawing off the blood from the cisternal area. Some are strongly opposed to therapeutic repetition of lumbar punctures, thinking that the value of these punctures has been over-rated and maintaining that Nature does just as well without interference, or even better

Borok goes so far as to say that lumbar puncture in the treatment of subarachnoid hemorrhage is "absolutely contraindicated", even for diagnosis he rejects it unless the clinical examination alone will not establish it, in which event he insists upon limiting the amount of cerebrospinal fluid withdrawn to 1 or 2 c.c. In our experience here, though in some cases a single lumbar puncture may suffice, in others repetition of lumbar puncture has been helpful in treatment provided the precautions mentioned have been observed.

After the acute symptoms have passed, the patient should be kept quietly in bed for at least eight weeks to permit of repair of the vessel wall, after which he may be allowed in a chair for an hour the first day, two hours the second day, and three hours the third day, then he may be allowed to walk about a little, avoiding, however, any sudden physical exertion or strong emotion. And since subarachnoid hemorrhage is prone to recur in patients who have had one attack, the mode of life should be carefully regulated ever afterward. The patient's habits should be definitely prescribed, with avoidance of any excess of alcohol or tobacco. Constipation with straining at stool should be guarded against. The prognosis is relatively good, however, and more than 50 per cent of the cases recover if treated in the way mentioned.

PERIARTERITIS NODOSA *

By FREDERICK R LUMMIS, M D, F A C P, *Houston, Texas*

As long as the exact status of periarteritis nodosa remains undetermined it will continue to hold the attention of the profession, as it has since the first description approximately 70 years ago. Many cases have been reported in excellent detail, the pathological picture well defined, the experience of the workers abroad and on this continent completely summarized. Bacteriological studies and animal inoculations have not given uniform results. Lately the clinical side has received a major emphasis in the attempt to formulate a picture more easily recognized during life and, perhaps, at an earlier stage of the disease.

Of uncertain etiology, periarteritis nodosa seems to be related to the rheumatic group of diseases, its coexistence with rheumatic endocarditis being noted too frequently to be disregarded^{1,2,3}. Apparently divergent views, that it is due to a filterable virus, that it is a form of hyperergy to some bacterial organism, that it is closely related to rheumatic fever, may not be irreconcilable. Schlesinger and Signy⁴ have lately presented experimental evidence of a virus as a causative agent in acute rheumatism, and Swift, Derick and Hitchcock⁵ have suggested that rheumatic fever itself is a hyperergy to a non-hemolytic streptococcus. In the same patient the distinguishing marks of periarteritis nodosa and of rheumatic fever may both be found, in other instances "the lesions of small vessels in rheumatic fever are so similar microscopically to some of the pictures in periarteritis nodosa that it would be difficult to distinguish the two"⁶.

In some instances the gross appearance of the lesions permits of identification and the diagnosis has been made clinically during operation. The presence of nodules and aneurysms along the course of the middle-sized arteries gives a characteristic appearance, the arteries of the mesentery being peculiarly open to inspection. The diagnosis is often, however, made only on microscopic study and it has been established by the routine postoperative examination of specimens of the appendix, gall-bladder, kidney and vas deferens. When the disease is clinically suspected, examination of excised nodules, skin or muscle is often confirmatory, but the absence of the diagnostic lesion in the biopsy does not preclude the existence of the condition in the arteries of the internal organs where the lesions are most often found, particularly in the kidney, mesentery, liver and heart. The arteries involved are the middle-sized ones, those of the size of the coronaries and less, the large arteries and the capillaries escaping. The condition may be localized to a small area or widely distributed but, even in the latter instance, the arterial changes are not continuous along the entire length of the artery but appear at different levels, the lesion beginning and ter-

minating quite abruptly. Apparently the toxic agent follows the periarterial lymphatics and attacks the artery at the site of entrance of the vasa vasorum. This distribution is not characteristic of periarteritis nodosa alone, Klotz⁷ having shown a similar situation of lesions in typhoid fever, *Streptococcus viridans* infection, etc. However, the character of the lesion developed in these areas is pathognomonic. The earliest and mildest lesions consist of an exudate in the adventitia—a non-suppurative inflammation. A further degree initiates the

FIG 2 Hyalinized thrombus filling one small vessel and partially occluding the other

striking and typical picture, a hyaline degeneration of the media with little or no cellular infiltration. Continuation of the toxic action is followed by fragmentation of the elastica, loosening and exfoliation of the intima, weakening of the entire wall and the formation of aneurysms with thromboses of the hyaline type and canalization of the clot. Repair may take place at any stage so that fibrosis may occur before the formation of aneurysms, in which case the clinically important nodules are not formed, or, the condition may progress to aneurysmal rupture with formation of ecchymoses into the skin or fatal hemorrhage.

rhage into some of the cavities, depending on the particular arterial areas involved. The veins are sometimes affected but do not form aneurysms or nodules.

The disease is rare, Klotz finding no example in over 3,000 autopsies until two patients suffering from the disease were admitted to the hospital on the same day and went to autopsy within four weeks of each other. Lamb⁸ saw two cases within a year, but a review of the sections of all cases of nephritis occurring at the Presbyterian Hospital over a period of six years showed no case of periaortitis nodosa. Bernstein⁹ reports three cases from the Johns Hopkins Hospital and the finding of four other instances of the disease in the review of 13,000 autopsies. It is seen in children and the aged, in both sexes but most often in males in the middle years, in many races.

The recognition of the disease during life has been exceptional. At times the course is acute, of only a few days' duration, or dramatic, presenting only the picture of its surgical complications, intra-abdominal hemorrhage or intestinal obstruction, which overshadow the underlying condition. In these fulminant cases a proper diagnosis is not to be anticipated before operation. But other cases evolve more leisurely and permit a more careful review of the bizarre features. Careful analyses of the reported cases and vivid representation of the clinical pictures by students of the disorder have established criteria that permit the *intervivum* diagnosis, at least in the more fully developed stage. The basic symptoms are chlorotic marasmus, peripheral neuritis, nephritis and gastrointestinal complaints. The progressive weakness and the sense of ill-being are prominent, anemia may or may not be conspicuous. To these symptoms of multi-system disease various other apparently unrelated phenomena are added. A febrile temperature is almost always found, and edema, perhaps fleeting and not necessarily dependent, is frequently noted. Pain in the muscles and joints is usual, the pulse is often accelerated and the blood pressure elevated. Leukocytosis is practically always seen if counts are repeated, and, although eosinophilia is not always present, its occurrence is suggestive. Palpable nodules and ecchymoses may be seen along the course of the arteries, the liver is usually palpable, the spleen sometimes. Many combinations of these findings are sufficiently unusual to suggest biopsy study.

The outcome is almost invariably fatal and no more favorable reports are at hand than of those few who have gone into remission. One of Aikin's cases¹⁰ is particularly illuminating, and, at the same time discouraging, in that the patient recovered from the acute phase of the disease and four years later died from its scars—with a generalized occlusive picture, ischemia of the major organs and function impaired below the vital level. Autopsy showed no acute process of the disease. It is not unlikely that there exists a form milder than the usual fatal one but it is at present below the diagnostic level.

The manner of exitus is dependent upon the course of the disease and the distribution of the lesions. With a slow sclerosing process, the termination may be that of vascular nephritis or of cardiac failure. Most often it is sudden from arterial rupture and hemorrhage, frequently intra-abdominal, perhaps meningeal or pulmonary. The hemorrhage may be beneath the capsule of the liver or the spleen. Mesenteric thrombosis is not rare and bronchopneumonia and pericarditis have been recorded as terminal agents.

CASE REPORT

R C B, an unmarried clerk, 40 years of age, presented himself for examination at the office September 18, 1935, complaining of fever, numbness of the right foot, loss of weight, strength and endurance, and of an indescribable sense of ill-being.

Present Illness He had not felt well all spring, there had been soreness in the joints and muscles without swelling, he was constipated, and he had suffered from an attack of a perennial type of hayfever. The previous June 10 he had gone to Mississippi on vacation but felt too badly to hunt or fish according to his custom, and, noticing the fever, took quinine for two weeks without relief, he then consulted a physician who prescribed atabrine. The fever was interrupted but soon returned and persisted. He returned to his work but progressively felt weaker and less able to perform his duties efficiently. In August "the cords" above the testicles swelled for one day, on September 7 the right foot went to sleep, the ankle swelled for a few days and felt like a spasm, without injury or discoloration. The swelling soon subsided but the numbness persisted. During the summer he lost 16 pounds in weight, the temperature during this period ranging from 99 to 101° F.

Past History Raised in Mississippi, he went through measles, mumps and whooping cough. At nine years he was sent to a hospital in New Orleans with "flux." At one time, together with all his classmates who consented, he was given treatment for hookworm but he does not recall a stool examination. There was some history of malaria in childhood and he was in the University of Virginia Hospital for this condition at 18 years of age and took quinine for some time afterwards. At 23 years he acquired a specific urethritis for which he was adequately treated. For 15 years afterwards he was occasionally seen medically for partial impotence and five years ago atrophy of the veru montanum was noted. There was some question as to whether or not strong silver applications had caused the condition. At this time he expressed the opinion to the attending physician that he was becoming senile at an early age. At 22 years he first suffered from a perennial type of hay fever, followed by asthma. At that time he was working in an oil refinery, and exposure to the fumes of sulphuric acid was considered so much a factor that he abandoned his work. Six years ago he was given skin tests for the usual excitants by Dr. A. E. Greer and studied carefully. He reacted to a number moderately and a diagnosis of hypersensitiveness, respiratory, alimentary and cutaneous, was made and a diet constructed. Dr. Greer very kindly supplied the data of this examination and the laboratory and physical examinations were practically negative except as outlined. He remained on the diet for about one year, discarded it then but had no further asthmatic paroxysms. Tonsillectomy was done 8 years ago because of tonsillar infection and 5 years ago he had hemorrhoids of mild degree. He did not have rheumatic, scarlet or typhoid fever. Each winter a week's "flu" was suffered. There was little appetite and, if food were forced, a feeling of pressure and discomfort was experienced. The diet was well balanced. There had been no jaundice, no colic, no hematuria. He thought the stools were at times tarry. Best weight was 148 pounds during the war, when first seen it was 127.5. He took little exercise, but his wind was not good. He was fidgety and easily fatigued. Alcohol, tobacco and coffee were used very moderately.

Family History The father is still a locomotive engineer at 72, one brother and two sisters are living and well. The mother died at 60 of arteriosclerosis after an illness of only one week in which "brownish spots" were conspicuous.

Physical Examination A sandy complexioned man of middle age, well educated, alert and not acutely ill in appearance. Height 65¾ inches, weight 127½, temperature 99°, pulse 76.

The pupils reacted to light and distance, the sclerae and conjunctivae were clear, there was no nystagmus, no exophthalmos, no ptosis or ocular palsy. The nares were open, the facial muscles normal, no mastoid tenderness was present and there were

FIG 4 Arteriole without coagulum showing early swelling of intima and infiltration of the media and adventitia with plasma cells and lymphocytes

no tophi and no discharge from the ear. No sinus tenderness was elicited. The pharynx was negative, the tonsils had been removed with some lymphoid return. Pyorrhea, grade 1, was present, there were no devitalized teeth. The tongue was protruded in the midline without tremor or atrophy. The sinuses transmitted light clearly. The cranial nerves were negative.

There was no adenopathy. The thyroid was just palpable and otherwise negative. The spine was straight, without tenderness.

The chest was well-formed, anteriorly, the upper right lagged, the bases expanded freely, the breath sounds were of lessened intensity and no râles were heard before or after cough. The heart was not enlarged, the left border being 9 cm from the mid-sternal line. The sounds were of good quality, the rhythm regular, no murmurs were heard. There was no dyspnea, no cyanosis, no abnormal pulsations. The blood pressure on two readings was 140 mm of mercury systolic and 84 diastolic, and 134 systolic and 84 diastolic.

The scaphoid abdomen showed no surgical scars. The right kidney was palpable on deep inspiration but not tender, the spleen came down on inspiration, the tip was easily outlined and tenderness was considerable. The edge of the liver was not felt. The abdominal and cremasteric reflexes were present.

Very slight pretibial edema was noted. There was some atrophy of the calves and tenderness on pressure on these muscles. The patellars were present and normal. Vibration sense was present, as was two-point touch. No Gordon, Oppenheim, Babinski or clonus were found. Temperature and position normal. On the outer side of the right foot, below the external malleolus and extending the length of the foot, an area of hypesthesia was outlined. Likewise there was loss of acute touch sensation on the pads of the toes on the plantar surface, and in the nail region on the dorsal. No foot or wrist drop was present, station, gait and coordination normal. The patient stated that the hands went to sleep but there was no objective sign of neuromuscular disturbance.

The testes and prostate were atrophied. Nothing abnormal in the epididymis was found. Rectal examination was negative.

A casual specimen of urine was negative except for low gravity. The blood showed hemoglobin 92 per cent, red blood cells 4,580,000, white cells 11,300, with polynuclears 55 per cent, small lymphocytes 29, large lymphocytes 3, large mononuclears 2, eosinophiles 9 and basophiles 2. The Wassermann and Kahn tests were negative.

Summary This was an unusual picture, one not seen before by the examiner. The patient may or may not have had hookworm disease, he had had malaria in previous years but in the present episode he had failed to obtain expected relief from quinine and atabrine. He had had some of the common infections, he had been found allergic to certain excitants and had had rather unusual relief from asthma. A middle-aged man, with a continuous fever of three months' duration, complaining particularly of marasmus, presented symptoms of multisystem disease: asthma and tendency to dyspnea on exertion, distress after eating a meal of the usual size, and perhaps tarry stools, paresthesias and muscular atrophy, a high normal blood pressure and an increased pulse pressure, a urine of low gravity. In addition there were evanescent swellings of the ankle joint and epididymis, and there was a moderate leukocytosis and a mild eosinophilia. This picture seemed to fit in with the description of periarteritis nodosa, although no nodules had been discovered, there was no anemia and involvement of the gastrointestinal and renal systems was minimal. It was understood that trichinosis might present a similar picture but the chronicity of this case was against that diagnosis. A tentative diagnosis of periarteritis nodosa was made and on September 25 a portion of the right gastrocnemius muscle was removed under local anesthesia by Dr Herbert Poyner and the specimen given to Dr Violet Keiller for examination.

FIG 5 A and B Hyperplastic intermyofibrillar spaces with three pigment cells
 Two of these are shown in figure 5B
 Loss of striation in muscle fibers near lesion

Laboratory Studies While the sections were being prepared the following laboratory procedures were followed out. A second blood count showed leukocytes 8,900 with 7 per cent eosinophiles. All slides were negative for malaria. Blood chemistry: Icterus index 6.8, blood sugar 88.0 mg per cent, non-protein nitrogen 34, creatinine 1.72, uric acid 3.6, chlorides 520. Glucose tolerance: Fasting 88 mg per cent, one-half hour 130, one hour 149, two hours 200, three hours 154. Phenolsulphone-phthalein: one hour 50, two hours 10. Agglutination against typhoid, para A and B, abortus, proteus $\times 19$, all negative. Stool pH 7, liquid, brown, trace of bile, no blood, small amount of mucus and detritus, no ova or parasites. Prostatic smear: No pus cells, occasional epithelial cell. Basal metabolic rate plus 19. Blood culture negative. The electrocardiogram showed a rate of 68 with normal complexes.

Roentgen-ray of chest (Dr McDeed). Costophrenic angles clear. Evidence is seen of adhesions on the right dome of the diaphragm. Left dome clear cut. There is thickening of the pleura between the right upper and middle lobes. Apical regions relatively clear. No evidence of active tuberculosis or other infectious process.

Ophthalmoscopic examination (Dr Haden). "The retinal veins of the right eye were somewhat tortuous, the arteries very tortuous. In the neighborhood of the disc the artery light streaks were exaggerated, but further out in the retina they became less distinct and finally disappeared. The arteries were not sharply defined and were bordered by a fuzzy streak, which suggested a disturbance of the lymph spaces. Where the arteries crossed the veins there was a decided depression, as is seen when the arteries have become harder. One minute vessel, a vein, showed three or four minute red swellings along its course. The fundus as a whole presented a fuzzy appearance and its details were not sharply cut. The fundus of the left eye presented similar appearances of the blood vessels to those seen in the right, but not so marked. The appearances of the vessels of either eye were those seen in arterial degeneration of a moderate degree."

When the slides had been studied Dr Keiller returned a diagnosis of periarteritis nodosa. Because of the known interest in this disease of Drs Middleton and McCarter of the University of Wisconsin, slides with the history were sent there and an opinion requested. Dr McCarter wrote under date of Oct 29, in part, as follows, and his courtesy is hereby gratefully acknowledged: "The biopsy is eminently satisfactory, enough tissue having been taken to allow the pathologist to make a good examination. The larger arterioles show some reaction typical of a rheumatic infection and two small arteries contain typical lesions of periarteritis nodosa. These are fairly acute, and, in view of his present fever, I believe that a poor prognosis is justifiable."

Subsequent Course The temperature in the last week of September ranged from 98° in the morning to 101° in the evening. On October 18 the blood count showed only 3,700 leukocytes with one eosinophile. In the middle of October he was hospitalized and given artificial fever without notable beneficial result. From October 19 to November 11, the period of hospital stay, except for the periods of therapeutic fever, the temperature was of the saw-tooth, septic type, from 98.6° to 101°, the pulse not following the elevation closely and remaining between 90 and 100. The blood pressure was recorded as 142/80 mm of mercury, 160/108, it then fell to 138/80 and later rose to 170/90 on November 6. This fall in the blood pressure preceding a second rise has been commented on by Bernstein. The blood counts showed 8,200 to 10,800 leukocytes with eosinophiles 6.5 per cent and 7.5 per cent respectively. The hemoglobin dropped to 76 per cent and the red cells to 3.84 millions on November 6. Further blood cultures and subcultures were negative. The urine continued to be of low specific gravity, 1.017 being the highest and this on only one occasion. Traces of albumin were present.

FIG 6 Weigert elastic tissue stain. Fragmentation of elastica shown in arteriole. The unstained pigment cells show prominently within lumina of both vessels.

A small scarlet spot appeared on the inner side of the right calf, not nodular, not tender, becoming brown the next day. The spleen was not palpable after the first few days of observation. On dismissal from the hospital he was placed on neoarsphenamine weekly because of reported benefit from arsenic. On November 23, the blood showed a hemoglobin of 92 per cent, red blood cells 4.78 millions, leukocytes 17,300, polynuclears 85 per cent, small lymphocytes 14, large mononuclears 1 and an absence of eosinophiles. Coincidentally the temperature approached normal and remained there with only an occasional afternoon rise to 100°. The weight loss was eight pounds in three months. A second electrocardiogram was again negative. With the normal temperature there was no subjective improvement. A note on December 15: "It might be hoped from the decline in the temperature that a remission is to be expected. This is probably merely a hope for the patient has not experienced the relief from his symptoms that should accompany a true remission. He states he feels 'as if every cell and fiber of the body were sick.'" No nodules were demonstrated along the course of the arteries, in December there was a questionable one in the right pectoral muscle which was slightly tender. On December 21 he came to the office and stated that he at last thought he could detect definite improvement. He felt better and a persistent, nagging headache had disappeared. Blood pressure was 180 systolic and 100 diastolic, the temperature normal. That afternoon he was found on the floor of his living room in convulsions. These were of a generalized character, and three or four occurred in succession. He did not regain consciousness and died in the ambulance on the way to the hospital. Postmortem examination was refused.

CONCLUSIONS

A case of periarteritis nodosa is reported. This was of such chronicity and extent that a diagnosis during life could be made and confirmed by biopsy.

The striking features were the long period of comparative ill health followed by the onset of persistent fever, peripheral neuritis, muscular atrophy, renal impairment, gastrointestinal symptoms and marasmus.

The use of arsenic brought the temperature to a normal level without relief of symptoms and the disease progressed to its accustomed sudden and fatal termination.

Acknowledgment and thanks are accorded Dr. G. C. Lechenger for the photomicrographs.

NEISSERIA CATARRHALIS ENDOCARDITIS

By R. MANNING CLARKE, M D, F A C P, and ROBERT B. HAINING,
B S, M D, *Los Angeles, California*

THAT vegetative endocarditis is due to microorganisms conveyed to the valves through the veins from external foci was first consistently proposed by Emmanuel Winge in a report to the Norwegian Medical Society in 1869. In this country, probably the first demonstration of the infectious nature of acute endocarditis was made before the Chicago Pathological Society by Christian Fenger in 1879. In 1881 Osler showed the New York Pathological Society microscopic preparations from endocardial vegetations containing minute bodies resembling bacteria. However, at this time members of the Society, while accepting the presence of the bacteria, were reluctant to regard them as the cause of the vegetations. They were inclined to believe that the bacteria were merely attendants of the disease, or possibly postmortem invaders, without pathogenic significance. Osler himself seems to have concurred with this view, though four years later his writings show that he fully recognized the infectious nature of the lesion.

Accurate determination of the causative bacteria in endocarditis began approximately at the turn of the century, and in the intervening years many organisms have been incriminated. In acute endocarditis, the principal offenders are well known pathogens, usually the pneumococcus, *Staphylococcus aureus*, gonococcus, or hemolytic streptococcus. Infrequently an organism ordinarily non-pathogenic for man is shown to be the *materia morbi*.

With the exception of the gonococcus and the meningococcus, endocarditis due to Gram-negative diplococci is rare. Examples of the disease caused by *Neisseria pharyngis sicca* have been reported by Schultz,¹ Shaw,² Graef, de la Chapelle, and Vance,³ and Goldstein,⁴ but the following case is, as far as we know, the only recorded instance in this country due to *Neisseria catarrhalis*.

CASE REPORT

History M. S., a Japanese girl, aged 15, referred by John Wahlen, M D, of Montebello, California. The patient knew of no definite childhood sickness, but once had been told she had a "leaky heart." The family history was not significant.

About October 30, 1933, she was seized with a chill, followed by fever and headache. She noticed a recurrence of these symptoms several times, and on November 25, a doctor was called who took blood for culture. This culture showed no growth, but the girl did not improve and December 7 she was admitted to the White Memorial Hospital. Her complaints while hospitalized were mainly of frequent pain in the chest and a stubborn cough with little sputum. Several times she complained of severe pain in the right upper abdominal quadrant, for which no cause could be ascertained.

Physical Examination The physical examination revealed a slightly pale, fairly well-nourished Japanese girl. On numerous occasions coarse râles were noted in the right lung base, posteriorly. The breath sounds were diminished in the left base, those heard over the upper lobes of both lungs seemed normal.

The heart was enlarged to percussion. The rhythm was regular. A loud systolic murmur was heard best over the pulmonary area, where there was also a palpable thrill.

* Received for publication March 24, 1936.

From the Departments of Medicine, College of Medical Evangelists and the Los Angeles County Hospital.

The abdomen was tender on pressure, particularly in the right upper quadrant. The uterus and adnexa seemed normal. Neurologic examination was negative.

The white blood cell count on admission was 31,250 per cu mm with 92 per cent polymorphonuclear neutrophils. The red blood cells numbered 3,600,000 per cu mm with 60 per cent hemoglobin. Urinalysis was essentially negative. Roentgen-ray of the chest showed evidence of partial consolidation in the right lower lung field. The blood Wassermann was negative. Repeated blood specimens were taken and a Gram-negative diplococcus was recovered in pure culture.

Course in Hospital Her temperature curve was septic in type, ranging from 97° F to 105° F. She became progressively weaker and toward the end somewhat delirious. She died January 12, 1934.

FIG 1 Section through vegetation from pulmonary valve showing bacterial colonies ($\times 60$)

Autopsy O B Pratt, M D performed the autopsy in an undertaking parlor where there were no facilities for weighing the organs.

The body was that of an emaciated Japanese girl. No petechiae, edema, or scars were noted.

The pleural cavities contained no fluid. Over the pleural surface of both lower lobes there were patches of fibrinous exudate. The upper lobes of both lungs were crepitant and the cut surfaces dry. Both lower lobes were heavy, dark red in color, and bloody fluid exuded from the cut surfaces. In the right lung two infarcts were found, roughly pyramidal in shape, each measuring about 3 cm in greatest length. On pressure over the lungs, purulent fluid exuded from the cut ends of the branches of the pulmonary artery.

The pericardium was smooth and glistening. The heart was only slightly larger than normal. The tricuspid valve measured 10 cm in circumference, and near the

margin of one of its leaflets there was a raised pink nodule 3 mm in diameter with a rough surface. A large, light brown, friable vegetation filled the conus arteriosus and extended 2 cm beyond the pulmonary valve into the pulmonary artery. Between the vegetation and the valve ring were two small passages, through which blood had apparently been transmitted. The cusps of the pulmonary valve were not deformed. There was slight ulceration at the site of the attachment of the vegetation, which was separated rather easily from the valve and the heart wall. The mitral ring measured 8 cm in circumference, and on one of the valve leaflets a nodular vegetation, 4 mm in diameter, was found at the line of closure. This was broken off in handling, leaving an ulcerated surface. The aortic valve appeared normal.

The liver was somewhat larger than normal and the cut surface was reddish brown. The spleen was about four times normal size. Its pulp was extremely soft and was dark red in color.

No other gross changes of significance were observed.

MICROSCOPIC EXAMINATION

Vegetation of the Pulmonary Valve Sections showed amorphous eosin staining material containing scattered leukocytes. At the free surface were fibrin and many leukocytes. Colonies of bacteria, apparently micrococci, staining lightly with hematoxylin, were seen near the surface as well as deep in the vegetation.

Tricuspid Valve Sections showed an ulcerated surface. The base of the ulcer was heavily infiltrated with leukocytes, and there were a number of bacterial colonies resembling those seen in the pulmonary valve vegetations.

Lung Surrounding an area of infarction, the alveoli were filled with eosin-staining fluid, containing some fibrin. Other alveoli were filled with blood and some were packed with leukocytes. A few colonies of bacteria were seen, each in close relation to a blood vessel. Some arteries were thrombosed and bacterial colonies were seen in the thrombi.

Liver There was evidence of marked chronic passive congestion and some fatty degeneration.

Spleen The findings resembled those of acute splenic tumor.

Kidney Some adhesions were noted in Bowman's capsule and there was an apparent increase of endothelial cells of the glomerulus. The tubular epithelium showed cloudy swelling. Some areas of interstitial tissue were infiltrated with small round cells and leukocytes.

BACTERIOLOGICAL STUDIES

All blood samples taken hourly for 24 hours on December 8 yielded pure cultures of a Gram-negative diplococcus. The number of organisms obtained varied from 1 to 3 per c.c. of blood. An identical strain of organisms was recovered in pure culture at autopsy from purulent material in the thrombosed pulmonary arteries.

On solid medium the colonies were small, rounded, firm, adherent, opaque, colorless, and at first smooth. Older colonies tended to have irregular margins and wrinkled surfaces. Subcultures were made on glucose, meat infusion agar, blood agar, plain agar, Loeffler's blood serum, and dextrose brain broth, on all of which the organism grew readily at 37.5° C. and at room temperature. No gas or acid formed in dextrose, inulin, or mannite. No pigment formed on any medium used. Except in medium containing brain, the cultures soon died, even when frequent subcultures were made. The conclusion was that the organism was *Neisseria catarrhalis*.

Accordingly the cause of death was given as acute bacterial endocarditis due to *Neisseria catarrhalis*.

COMMENT

In 1932, Curtis⁵ reported the case of a physician who, following tonsillectomy, developed acute polyarthritis. *Neisseria catarrhalis* was recovered from cultures of this man's blood and a diagnosis was made of "acute polyarthritis, acute endocarditis, and bacteremia of *Micrococcus catarrhalis* origin." The record of this patient's illness closely resembles that of a Mr L G, a white male, 21 years of age, who was admitted to the Los Angeles County Hospital, February 7, 1935, complaining of precordial pain and recurrent bouts of chills and fever. For weeks his temperature ranged from 97° F to 105.5° F, and of 11 blood cultures, eight were positive for *Neisseria catarrhalis*. A soft systolic murmur was heard at the apex, petechiae were seen on chest and abdomen, and the clinical diagnosis was acute endocarditis due to *Neisseria catarrhalis*. In contrast to Curtis' patient, who received sodium iodide, neosalvarsan, salicylates, and cinchophenic acid, this patient was given graduated doses of a *Neisseria catarrhalis* vaccine, prepared from his own blood cultures by Dr Fisk, Bacteriologist at the Los Angeles County Hospital. From April 27 to May 10 this patient remained afebrile and, feeling much better, he insisted on leaving for his home in Texas. A letter from the local social worker, dated July 4, 1935, stated that he was doing light work.

Since both these patients recovered, the diagnosis of endocarditis was not established and we believe the case reported with autopsy in this communication is the first pathologically proved example of *Neisseria catarrhalis* endocarditis in this country.

In Europe a similar autopsied case of endocarditis due to this organism has been observed and described by Endres⁶. His patient was a farm worker, 47 years of age, with a definite history of rheumatic fever, followed by heart damage. At autopsy there was evidence of rheumatic involvement of the mitral and aortic valves. (Incidentally, our patient, while giving a history of a "leaky valve," proved to have no pathological evidence of rheumatic heart disease.) Small Gram-negative diplococci were seen histologically in a vegetation on the aortic leaf of the mitral valve. Similar organisms had been recovered from blood cultures and proved bacteriologically to be *Neisseria catarrhalis*. In this case there was a classical embolic glomerulonephritis. In our patient, since the vegetations occurred on the pulmonary and tricuspid valves, embolic phenomena were seen only in the lungs.

While *Neisseria catarrhalis* is found commonly in the upper respiratory passages, and usually possesses little virulence, under favorable circumstances it apparently may become pathogenic. For example, it has been recorded as the etiological factor in meningitis,⁷ pneumonia,⁸ and septicemia.⁹

SUMMARY

A case of fatal endocarditis due to *Neisseria catarrhalis* is reported. *Neisseria catarrhalis* is rarely pathogenic, and as the cause of vegetative endocarditis it must be extremely rare, for we are unable to find another example, with autopsy, in the literature of this country.

A resumé is given of a case of septicemia of *Neisseria catarrhalis* origin. This patient was thought clinically to have endocarditis, but he made a surprising and apparently complete recovery.

EDITORIAL

BIOLOGICAL FACTORS IN MALARIAL CONTROL

The recent sharp rise in the death rate from malaria in the United States¹ serves as a sharp reminder that the problem of malarial control in this country is not yet solved. To many of us, at least those of us who do not live in a malarial district, it is somewhat surprising to read that over 4,500 died from malaria in this country in 1934, and that the morbidity rate for that year was probably over 5,000,000 cases. Superficially the problem seems a simple one—exterminate the mosquito. Past experience indicates that any effective method of control does indeed depend on destroying the mosquito larvae or eradicating their breeding places. To accomplish this, however, we must know what species to attack, where to find it, and what weapons can be used effectively against it. Some of the complexities of this problem have been pointed out in an interesting way by Hackett².

Human malaria is transmitted exclusively by certain species of mosquitoes belonging to the genus *Anopheles*. It has been proved that about 40 (out of over 100) species may become infected with malaria and can transmit the disease to man under experimental conditions. Epidemiological studies have shown, however, that under natural conditions most of these species rarely convey malaria, and that 12 or 15 species are responsible for nearly all the malaria of the world. In a given locality, as a rule, only one or at most two or three species are of practical importance. The reasons for the failure of potential vectors of malaria to convey the disease under natural conditions are various. They can be determined only by a minute study of the habits of each species and its relation to its environment in each different region.

In some cases this depends upon the preference of the mosquito for animal rather than for human blood. In the eastern United States, for example, three potential vectors of malaria are abundant. Two of these (*A. crucians* and *A. punctipennis*) are relatively "wild" species, rarely enter houses, and by preference bite animals rather than man. *A. quadrimaculatus*, on the other hand, often enters houses, bites man and animals indifferently and is responsible for nearly all the malaria in this region. The biting habits of the same species may differ in different localities. In the case of *A. maculipennis*, the principal vector in Europe, there are several races whose habits differ in this respect. The race in the coastal districts of Holland, which breeds in brackish pools, bites both man and animals indifferently, and malaria is endemic in these regions. A few miles inland there

¹ As shown by the collected statistics of the U. S. Public Health Service and emphasized at the Symposium on Malaria of the National Malaria Committee and the Southern Medical Association. South Med. J., 1935, xxviii, 736.

² HACKETT, L. W. Biological factors in malarial control, Am. J. Trop. Med., 1936, xvi, 341-352.

is a different race (distinguishable only by the bairred markings on its eggs) which breeds in fresh water and prefers animal blood. Here malaria is sporadic. In more primitive districts in which few animals are raised (as in central Russia) this race is driven to bite man and becomes a dangerous vector. For other reasons which are entirely unknown the same species (e.g. *A. subpictus*) may convey malaria in one region (in the East Indies) and not in another (in India), although it is abundant and bites man freely in both.

The character of the breeding places is even more important. *A. quadrimaculatus* in the United States breeds in quiet fresh water in pools or puddles, and where adequate drainage of such areas is possible, the pest can be eliminated to a large extent. This should be practicable for the larger communities, at least, since these mosquitoes rarely travel more than a mile from their breeding places. In Italy, on the contrary, the prevailing species breeds equally well in quiet or flowing water, and drainage does not affect it. In certain districts of Malaya in which the vector (*A. maculatus*) breeds in open flowing streams, by damming the streams and producing a series of pools it has been possible to eliminate this variety and replace it with harmless species. On the other hand in regions like Albania in which there are two vectors which differ in their choice of breeding places, the elimination of one, when a drought dries up the pools, is accompanied by an excessive breeding of the other in the shallow streams. The breeding habits of the same species may differ in different regions. Thus in Java *A. ludlowi* breeds only in salt water, and its depredations are confined to the coastal regions, while in Sumatra it breeds in fresh water and infests much of the island.

A radical change in the environmental conditions in a district may convert a potential vector, previously harmless, into a dangerous transmitter. This occurred when the cultivation of rice was introduced into Sumatra during the war. An epidemic of malaria broke out promptly, due to *A. hyrcanus*³. This possibility had been excluded, it was supposed, by the fact that this species breeds abundantly in the rice fields of Java and other neighboring islands and there it is not a transmitter.

In the United States the problem seems relatively simple. There is only a single important transmitter, and its breeding places can be eradicated without undue difficulty. The immediate obstacle is the prohibitive cost of carrying out such procedures on an adequately large scale. It is to be hoped that further study will reveal less costly methods of control. Unless it does, we may expect that malaria will continue, at least until the economic value of the peasant exceeds the cost of the public health measures necessary to protect him.

REVIEWS

American Martyrs to Science Through the Roentgen-Rays By PERCY BROWN, M D ,
F A C P , F A C R 276 pages, 15 5 × 23 5 cm Charles C Thomas, Baltimore
1936 Price, \$3 50

This small volume presents a brief sketch of the lives of an heroic group of Americans connected with the early history of the roentgen-rays. It is written in a readable style and brings to life those earnest, faithful scientists who, by every sacrifice, including that of life itself, made the advance of roentgenology possible.

Forty years ago this new science was conceived and it has been largely due to the valiant efforts of this illustrious group of men that roentgenology has advanced so rapidly to its present status. It is interesting to note the different channels by which these men entered the field, and their complete absorption in their work, even when suffering the most excruciating pain. Very few of the early pioneers were provided with any protection against the direct effect of the rays. Sometimes the face and chest, and more often the hands, were repeatedly exposed in order to make a satisfactory examination of the patient, or to exploit the "x-rays" in popular exhibitions.

The serious nature of their work so thoroughly dominated their thoughts that they had little consideration for their personal safety. These pioneers lived and died in relative obscurity. They gave their lives to the cause of science, and if ever the term Martyr should be applied, it belongs to them.

The author has inserted a simple glossary for the layman "to clarify the meaning of certain scientific terms impossible to avoid."

The author speaks with authority and modestly refrains from any personal allusions. Anyone interested in the progress of medicine will find this book both interesting and instructive.

H J W

The Pathology of Internal Diseases By WILLIAM BOYD, M D , M R C P , F R C P
Second Edition 904 pages, 16 × 24 cm Lea and Febiger, Philadelphia
1935 Price, \$10 00

In the second edition of this work the author has added many new sections, and major alterations have been made in other sections. The illustrations are excellent. References, especially to the more recent literature, follow each chapter. The author not only describes the morbid anatomy of internal diseases, but also links it to the clinical symptomatology presented by such diseases. At times he perhaps is more positive in his statements than would seem justified by the evidence at hand, and at times the clinical discussion leaves something to be desired. However, one hesitates to criticize what the reviewer considers so valuable a work. The style is forthright and the book throughout maintains its interest. It is highly recommended to students and to practitioners.

W S L , JR

Common Contagious Diseases By PHILIP MOEN STIMSON, A B , M D 437 pages,
14 × 20 cm Lea and Febiger, Philadelphia 1936 Price, \$4 00

The clear presentation of the subject matter contained within this manual is striking, for despite its conciseness, the author has avoided disjointed sequences and the impression of incompleteness that a reader is so often left with after reading abbreviated books. There is instead a personal feeling instilled so that the reader may easily imagine himself in the presence of the author.

The introductory chapter on "Infection and Immunity" is discussed mostly from its clinical relationship. The author deals understandingly with these topics, without becoming mired in hypothetical conjectures.

Diphtheria, Vincent's angina, scarlet fever, measles, rubella, pertussis, mumps, chicken-pox, small-pox, meningococcus meningitis and poliomyelitis are the diseases discussed as contagious. All aspects of these conditions are dealt with in an adequate manner. The newer work on the subjects is included and a practical critical evaluation offered. Adequate space is devoted to the various sera being used in both prophylaxis and treatment. Personal experiences are nicely blended in the discussion to confirm or throw doubt upon a conjecture. An adequate bibliography is included at the end of each chapter. A final chapter on the "General Management of Contagious Diseases" is included. And here, especially in the discussion of the management of "Contagion in the Home," is the practical attitude made most apparent.

Photographs and various charts are embodied in the text. Unfortunately the photographs of the exanthems are not colored, hence their value is relatively negligible.

The book is unreservedly recommended by the reviewer for the use of the medical student and practitioner.

J E B

The Human Foot By DUDLEY J MORTON 244 pages, 16 X 23.5 cm Columbia University Press, New York 1935 Price, \$3.00

This book is a most complete treatise on the foot and to a practicing orthopedist is most timely. If it should be read by a sufficient number of medical practitioners, shoe manufacturers, and chiropodists its value would be inestimable.

The book is divided into three parts, covering the evolution, the physiology, and the functional disorders of the human foot. Each part treats thoroughly the various elements of its topic by means of several or more chapters. The text is easy to read, is as free from technical language as is possible, and yet is thoroughly clear and easy to understand.

Part 1 is quite interesting and explains what may lie back of many functional foot disorders. Ordinarily, we rarely realize that the foot of today is expected to do many things for which it originally was not made and this particularly with the handicap of the modern shoe.

Part 2 analyzes thoroughly the varied and complicated activities of the foot in standing, walking, etc. Emphasis is laid upon the well known fact that a normal foot does not need "artificial aid in its function of stance and locomotion." People who have never worn shoes do not as a rule have the foot troubles we hear so much about. This chapter bears analysis and study and will well repay a careful reading. Active exercise is essential to foot comfort and efficiency.

Part 3 considers the possible effects of abnormal development and function, describes the clinical signs and symptoms of each type of disability, and lastly gives good suggestions as to treatment. Emphasis is laid upon the improper use of an arch support, especially of the rigid type. Redevelopment of the weakened structures is the theme of this section and this should be the basis of sound practice. Artificial aids should be used only as auxiliary measures until proof exists that the foot will not respond and must be "crutched" permanently.

All in all the book should be referred to frequently and should find a place in everyone's reference library.

A V

The Kidney in Health and Disease Edited by HILDUNG BERGLUND, M D, and GRACE MRDES, Ph D with the collaboration of G CARL HUBER, M D, WARFIELD T LONGCOPE, M D, and ALFRED N RICHARDS, Ph D, M D 754 pages, 16 X 24 cm Lea and Febiger, Philadelphia 1935 Price, \$10 00

This volume is the outgrowth of a symposium in 1930 on the structure and function of the kidney in health and disease. The project was initiated by Dr Hildung Berglund, then Professor of Medicine in the University of Minnesota. The contributions made at that time have been revised and brought to date by the participants in the symposium. There are 44 contributors and listed among them are many of the prominent investigators of questions pertaining to the kidneys. The book is divided into six parts and 41 chapters. The main divisions are concerned with the anatomy and physiology of the kidney, clinical aspects of renal functions, Bright's disease and other pathologic renal conditions, albuminuria and edema, ocular changes in Bright's disease, and clinical aspects of Bright's disease.

This volume affords an excellent example of what may be accomplished by welding together contributions by many outstanding investigators. It is an authoritative reference work. Each contribution is accompanied by a thorough bibliography. This is a volume which no one interested in kidney problems will wish to be without and any practitioner could read it with pleasure and profit.

W S L, JR

The Crippled and the Disabled By HENRY H KESSLER, M D 337 pages, 16 X 23 5 cm Columbia University Press, New York 1935 Price, \$4 00

Any study of the problem of the crippled and disabled is necessarily extensive and difficult due to the many types and combinations, both as to areas and senses involved, and to the age periods and variable reactions of each. Dr Kessler has very thoroughly reviewed the extensive available literature and has analyzed the facts presented from an unbiased standpoint. His suggestions for the correction of the situations as now found are sensible and sound.

The book is divided into seven parts, an appendix and a large bibliography. The disabled are considered generally in Part 1, where the problem as a whole is analyzed with appropriate comments as to the need for a change in the attitude of the disabled toward the community and vice versa.

Part 2 deals with the child problem both here and abroad. Much more definite progress has been made for children than for adults due to the appeal possessed by children and to the activities of fraternal and social organizations. Industrial advancement and the experiences of the War have led to a greater activity in providing care for disabled adults.

Parts 3 and 4 consider the industrially disabled and those injured in war. The care of these two groups has stimulated the development of improved physical and occupational therapy. Statistical tables and many references show the changing situations of these types. An appeal is made for a more universal consideration of the disabled by industry so that a trained cripple may obtain reemployment more easily.

The chronically disabled are considered in Part 5. Special emphasis is laid upon how their needs are and should be met.

The blind, deaf, and deaf-mutes are considered very briefly in Part 6, and the whole picture is summarized in Part 7.

An appendix gives a short summary of the various types of legislation in each State, at the end is a very complete and extensive bibliography which will be most useful to anyone who is interested in the problem of the disabled.

The book is an important addition to a reference library and is very appropriate at the present time.

COLLEGE NEWS NOTES

ADDITION TO THE LIFE MEMBERSHIP ROSTER

Dr Orville H Brown (Fellow), Phoenix, Ariz, became a Life Member of the College on June 10, 1936

GIFTS TO THE COLLEGE LIBRARY

Acknowledgment is made of the receipt of the following gifts to the College Library of publications by members

Dr J N Hall (Fellow), Denver, Colo—4 books, Volumes I and II, "Borderline Diseases," and Volumes I and II, "Textbook of Legal Medicine and Toxicology",

Major James S Simmons (Fellow), M C, U S Army—1 book, "Laboratory Methods of the United States Army" (Fourth Edition),

Dr Charles F Morsman (Fellow), Hot Springs, S D—2 reprints,

Dr Glenn D Carlson (Associate), Dallas, Tex—1 reprint,

Dr John P Hilton (Associate), Denver, Colo—1 reprint

MEETING OF THE NEW JERSEY MEMBERS

Under the Governorship of Dr Clarence L Andrews, Fellows and Associates of the College from New Jersey held a luncheon-meeting at the Claridge Hotel at Atlantic City on June 3 Dr Andrews acted as Chairman and Toastmaster Dr Ernest B Bradley, President of the College, Lexington, Ky, Dr O H Perry Pepper, First Vice-President, Philadelphia, Pa, Dr William D Stroud, Treasurer, Philadelphia, and Mr E R Loveland, Executive Secretary, made short addresses concerning various College activities Other guests present included Dr E J G Beardsley, of Philadelphia, Governor for eastern Pennsylvania, and Dr Lewis B Flinn, of Wilmington, Governor for Delaware Twenty-five Fellows and ten Associates from New Jersey were present

Dr George R Minot (Fellow), Boston, Mass, and Dr Hugh J Morgan (Fellow), Nashville, Tenn, were elected Vice-President and Secretary, respectively, of the Association of American Physicians at its annual meeting in Atlantic City, May 6

Dr W A Dearman (Fellow) has removed from Gulfport, Miss, to Whitfield, Miss, where he has assumed the duties of Assistant Superintendent of the Mississippi State Hospital

Dr Ralph Pemberton (Fellow), Philadelphia, addressed the Lehigh County (Pa) Medical Society at Allentown, April 14, upon Arthritis, he gave a Seminar at the Robert Packer Hospital, Sayre, Pa, May 27, on Arthritis, and he addressed the Medical Society of the County of Saratoga, New York, June 4, upon the same subject

Dr Joseph Hajek (Fellow), New York, N Y, has been elected Secretary of the Section of Medicine of the New York Academy of Medicine

Dr Hyman I Goldstein (Associate), Camden, N J, presented a paper on "Antispasmodic Therapy in Gastro-Intestinal and Biliary Tract Diseases" at the 170th annual meeting of the New Jersey State Medical Society, Section on Gastro-Enterology, at Atlantic City, June 4 His paper was discussed by Dr Samuel Weiss (Fellow), New York, and by Professor Charles M Gruber, of Philadelphia

Dr Goldstein also discussed constipation at the convention of the National Society for the Advancement of Gastro-Enterology at Atlantic City, June 5

At the annual meeting of the Arkansas Medical Society at Hot Springs National Park, Dr George B Fletcher (Fellow), Hot Springs National Park, was installed as President Dr Arthur G Sullivan (Fellow), Hot Springs National Park, was elected a Vice-President and Dr William R Brooksher (Fellow), Fort Smith, as Secretary

Dr Leon Unger (Associate), Chicago, addressed the Chicago Society of Allergy, May 18, on "Asthma in Children, Results of Treatment"

Dr William H Marshall (Fellow), Flint, Mich, has been elected President of the Northern Tri-State Medical Association

Dr James H Donnelly (Fellow), Buffalo, is President of the Buffalo Academy of Medicine

Dr Walter W Palmer (Fellow), Dr Alvan L Barach (Fellow), both of New York City, were lecturers on the program of the ninth annual postgraduate day of the Mahoning County (Ohio) Medical Society at Youngstown, April 30

Dr Edgar A Hines (Fellow), Seneca, S C, has been reelected Secretary of the South Carolina Medical Association Dr Hines has served as Secretary for 26 years

Dr Howard T Karsner (Fellow), Cleveland, Ohio, has been elected Secretary of the American Association of Pathologists and Bacteriologists at their annual meeting in Boston during April

Dr Jesse D Hamer (Associate), Phoenix, Ariz, was installed as President of the Arizona State Medical Association at its annual meeting recently

Dr Charles Wolferth (Fellow), Philadelphia, delivered a lecture on "Observations on the Mechanism and Clinical Interpretation of Heart Sounds" in connection with the annual postgraduate course of the Indiana State Medical Association at Indianapolis during April

Dr George P Pratt (Fellow), Omaha, Nebr, presented a lecture on coronary disease at the regular meeting of the Southwestern Iowa Postgraduate Medical Society in the spring

Dr Soma Weiss (Fellow), Associate Professor of Medicine at Harvard Medical School, was one of the speakers on a cancer symposium conducted in connection with the 84th annual session of the Maine Medical Association in Rangeley, June 21 to 23

Harvard Medical School will observe its Tercentenary, September 14 to 15. The Harvard Medical Alumni Association will hold its annual meeting and dinner in Vanderbilt Hall on the evening of September 15, the dinner having been postponed from its usual time in June to encourage participation of as many graduates as possible in the Tercentenary celebration. Dr George R Minot (Fellow) will act as Chairman of a symposium on nutrition and the deficiency diseases, Dr James H Means (Fellow) will act as Chairman of a symposium on the endocrine glands.

The Medical Society of New Jersey held its 170th annual meeting at Atlantic City, June 2 to 4, under the Presidency of Dr Marcus W Newcomb (Fellow), Browns Mills. Among guest speakers were Dr Israel M Rabinowitch (Fellow), Montreal, "Medical Complications in Diabetes Mellitus," and Dr Arthur C Christie (Fellow), Washington, D C, "Medical Progress Under the Leadership of the Medical Profession."

Dr Ross McC Chapman (Fellow), Towson, Md, was elected President-Elect of the American Psychiatric Association at its annual meeting in St Louis, May 4 to 8.

Sir Frederick G Banting (Fellow), Toronto, and Dr Joseph B Collip (Fellow), Montreal, addressed the annual meeting of the Canadian Medical Association at Victoria, B S, June 22 to 26, on "Silicosis Research" and "Significance of Recent Investigations of the Ductless Glands," respectively.

Dr F M Pottenger (Fellow), Monrovia, Calif, presented the Phi Rho Sigma Lecture at the University of Colorado School of Medicine, Denver, May 7, on "Physiological Approach to the Diagnosis and Treatment of Tuberculosis."

The Academy of Medicine of Washington was organized April 28, with Dr William A White (Fellow), President, Dr Earl B McKinley (Fellow) and Dr Matthew W Perry (Fellow) as Directors. The membership will be limited to 60 resident members and 30 associates or non-resident members. Membership is open to non-medical as well as medical men, since no special distinction has been made between the medical sciences and allied sciences.

Dr Guy C Jarratt (Associate), Vicksburg, Miss, has been elected one of the Vice-Presidents of the Mississippi State Medical Association.

Dr Edward Rose (Fellow), Philadelphia, addressed the Gloucester County (N J) Medical Society recently on "Basal Metabolism and Its Relation to Disease."

Dr Louis E Viko (Fellow), Salt Lake City, is President-Elect of the Utah State Medical Association.

OBITUARIES

DR GERTRUDE M JOHNSON

Dr Gertrude M Johnson died January 29, 1936, of lymphatic leukemia, aged 56 years.

Dr Johnson was born in Minneapolis, Minn, December 12, 1879. She entered Battle Creek Sanitarium in 1898 in the School of Nursing, graduat-

ing in June 1900 She began the study of medicine in the American Medical Missionary College in 1900 and graduated in 1904, and since that time has been employed almost constantly as a member of the medical staff of Battle Creek Sanitarium

In addition to her medical staff duties, she devoted time for several years to teaching in the School of Nursing During her career in medicine she made two rather extended visits to Europe for postgraduate work, visiting both England and the Continent

Dr Johnson was a keen observer and diagnostician In addition she devoted considerable time to research work, and produced several articles of value during the last few years She completed a report on an interesting case during her last illness

She was a member of the American Medical Association, of the Michigan State Society, of the Calhoun County Society, and also a Fellow of the American College of Physicians She was greatly beloved by her patients, many of whom came to see her year after year because of the kindly interest she showed and the effort she made to neglect nothing that might afford them relief

M A MORTENSEN, M D , F A C P

DR CARL FREDERICK MOLL

Dr Carl Frederick Moll of Flint, Michigan, an Associate of the College since 1926, died suddenly of a heart attack in Detroit on May 1, 1936, at the age of 64 years

Dr Moll graduated from the Saginaw Valley Medical College in 1899, and started practice in the Upper Peninsula in Michigan Shortly before the war, he moved to Flint, Michigan, and practiced as an internist in that city since that time

Besides enjoying one of the largest practices in his city, Dr Moll found time to give much to the medical organizations of the state and nation He was Past President of the Marquette County Medical Society, and held numerous offices in the Michigan State Medical Society, including that of President From 1926 to 1935, he was a member of the House of Delegates of the American Medical Association His professional appointments were numerous He was a member of the staff of St Joseph's Hospital and of the Women's Hospital, as well as being President of the Staff of Hurley Hospital, and Physician to the Michigan Home of the Deaf

Dr Moll was well known both as an internist and as a citizen of the state A man of warm friendliness and unselfish loyalty, he was well beloved by all of his fellow physicians, who will miss keenly his wise counsel and able leadership

HENRY R CARSTENS, M D , F A C P ,
Governor for Michigan

MINUTES OF THE GENERAL BUSINESS MEETING

DETROIT, MICH

March 5, 1936

The Annual Business Meeting of the College was called to order at the Book-Cadillac Hotel at 5 00 p m, Thursday, March 5, 1936, with President James Alex Miller presiding. Reading of the Minutes of the previous Business Meeting was dispensed with by resolution.

Dr William D Stroud, Treasurer, presented the following treasurer's report

"At the present time our total funds amount to \$157,329 00. This is distributed into Endowment, \$58,281 72 and the General Fund, \$99,047 47.

"The funds have been audited and the accounts declared correct by a certified public accountant. Our investments as originally purchased, in bonds, amounted to \$111,844 00. Their present value, as of February 28, is \$116,430 00, or, in other words, they show a book profit of \$4,285 00.

"Our stock investments amount to a purchase price of \$14,811 00 and their book value at present is \$17,902 00, showing a profit of \$3,091 00. Our bonds and stocks have increased in value \$7,377 00 since they were purchased. I think this gives the members of the College a very secure feeling as to our finances."

The treasurer's report was accepted and filed.

Mr E R Loveland, Executive Secretary, reported that up to this time 1,528 had registered at the Annual Meeting. He gave the following report on membership.

"During the past year 181 Fellows and 187 Associates were elected. That does not mean that the College has grown 368, because many of those elected to Fellowship were advanced from Associateship.

"During the past year, the Executive Offices had published the 1935 Directory containing the names of 5 Masters, 2415 Fellows and 818 Associates, total, 3238. Since the publication of the Directory on October 1, 1935, there have been 19 deaths, 10 resignations and 16 were dropped for delinquency (the number of resignations and the number dropped for delinquency was called to the attention of the general body, because the number was so small in comparison with the membership), 13 Associates were dropped for failure to qualify for Fellowship. With these elections and adjustments, the membership at this date was 4 Masters, 2565 Fellows and 843 Associates, total, 3412."

Mr Loveland reported that since the rule has been in effect that new candidates must first become Associates and serve a probationary period of three to five years, over 75 per cent of such Associates had qualified for Fellowship. Of the class of Associates elected in 1931, 78 qualified for Fellowship and 23 failed for one reason or another. In other words, about 77 per cent of those elected in 1931 succeeded in becoming Fellows.

In regard to Life Members, he reported that there had been a further increase, the number having reached 61 to date. He referred to the Life Membership Roster being displayed at the College Booth near the registration headquarters.

Mr Loveland further reported that a fairly large number of members visit the College Headquarters each year, and that in some instances he had been able to arrange programs of a medical character for visiting members, so that they could observe what is being done medically in Philadelphia. He invited members to visit the College Headquarters and to call on the College Offices for any assistance whatsoever that can be rendered. He thanked the members of the local Detroit committees who had helped so greatly in making the arrangements for the Detroit Session.

Dr James Alex Miller, President, on behalf of the Board of Regents, reported first upon the progress toward the establishment of an American Board of Internal Medicine for the certification of internists, that work had been organized under a joint committee of the American College of Physicians and the Section on the Practice of Medicine of the American Medical Association, the details having been worked out to such a point that the Board of Regents of this College had approved them, as far as the College was concerned, and the Committee was authorized to proceed. All that was necessary was the final approval of the American Medical Association, whereupon the Board will be ready to proceed with the regular installation of a method of certification of internists in this country. He expressed the prophecy that this will mean a long step forward in defining what internists really are and what specialists in Internal Medicine should be. He expressed the opinion that the work of this board will be of great help to the College in enabling it to make these examinations as a basic requirement for Fellowship. The work of this board will not in any way interfere with the activities of the College. Certification may be one of the requisites for admission to the College, but the College will undoubtedly always have other requirements for its Fellowship. This development will have a great influence in raising the standards of the practice of Internal Medicine in this country, the work of the College during the past year in sponsoring this board may be looked upon as of real significance.

The second subject discussed by President Miller concerned the finances of the College and various projects concerned therewith. He informed the members that over past years the College has been successful in accumulating a sum of money somewhat in excess of immediate needs. The Board of Regents has given serious consideration to this and has a definite program in mind, a program which in the future will enable the College to extend its usefulness and possibly at some future time to diminish definitely financial burdens of members, particularly in respect to initiation fees, which at present are \$80.00, having already been reduced from \$100.00. The College has been enabled to sponsor the American Board of Internal Medicine, because it had some available money. The College is going to finance all of the Board's work during the stage of its development, advancing the money until the Board is able to return it from the fees which will be exacted from those who take the examinations, and the College also has a plan of extending its other activities as it has financial opportunity to do so. Among these other activities may be the stimulation of clinical research among younger members of the profession by establishment of additional fellowships, also probably by the procuring of a suitable and dignified permanent home for the College. Furthermore, the Board of Regents has provided for the appointment of a committee to look into the details of other methods for the promotion of Internal Medicine. The procuring of a suitable home for the College will ensure permanency and add dignity to the organization. In conclusion, Dr. Miller expressed his appreciation of the cooperation the membership had shown in the arrangement of the Detroit Session, and for their interest and hearty cooperation during his term as President. He especially complimented the staff of the Executive Offices, the Executive Secretary, the Treasurer and the Finance Committee, stating it is due in no small measure to their efficient management that the College now finds itself in a position to expand somewhat in its field of usefulness in Internal Medicine. In conclusion he said in part:

"Now, personally, I wish to express again my own very deep feeling of appreciation of the great honor that you have conferred upon me in electing me to this office of President. It has been a year which has been most interesting and stimulating and one which I shall always remember with the greatest pleasure and which will always be a source of great satisfaction and will make me feel that, in being honored to be your President, there has been a year of productive effort and one of great satisfaction which I will always carry with me.

"I now come to a very pleasant duty as I lay down the responsibilities of the Presidential office. It is with very peculiar pleasure that I have the privilege of in-

ducting into office the incoming President We have in our new President a man whom we all love, a man who is outstanding in his devotion to the best interests of the practice of medicine, a man who has given, both in the Board of Governors and in the Board of Regents, the best that he has to the interests of this College We know what Ernest Bradley has been and, consequently, we are confident of what he will do for this College It is therefore with the greatest pleasure and happiness, Dr Bradley, that I turn over the responsibilities of this office to you" (Applause as all stand)

President-Elect Bradley "It really seems impossible that the time should ever come that I could stand here as your President, after the renowned men who have preceded me Of course, to those other men who have been elected as President, it was just 'one other honor,' but to me, of course, without having had these honors, my friends down in Western Kentucky don't know whether I have been elected President of the American Medical Association, of some great medical university, or even of the United States (Laughter) It grieved my best friends to think that I had been elected the President of some great medical university, or that I would have to leave Lexington as President of the College of Physicians I have tried to reassure them, so that if they get sick next year, they might come back to ask me about it

"I have been thinking that, looking up at the altitude, at least, of these two former Presidents, Dr Meakins and Dr Miller, that if this thing keeps up very much longer going down like it is now, along about 1938 or 1939 you will be even below sea level as far as your President is concerned (Laughter)

"I couldn't possibly tell you, of course, really how great an honor this is to me It is something, of course, I never dreamed of in my life I just hope that I can do the best I can I know that it will be difficult for any president to steer this old Ship of State very far wrong because if we make any mistakes or if we even shy off the course a little, we have a pilot on board all the time who will see to it that we don't go too near the rocks I refer to Mr Loveland, our Executive Secretary

"I hope that with the cooperation of the members of the Society, which I know I will get, and the help of the Board of Governors and the advice of the Board of Regents, I will be able to carry on I know that we have big things before us next year The College is beginning to stand for more and more every year, it is becoming recognized more and more, and I cannot tell you how much I am honored by your electing me to this office I thank you very much" (Applause)

Dr William Gerry Morgan, Secretary-General "Dr Miller, on behalf of the College, I have the privilege of presenting to you this token of our appreciation of your splendid accomplishments during your year as President" (Dr Morgan presents the retiring President with an official gavel, appropriately engraved)

Dr Miller "Mr Secretary-General, Mr President, Fellows of the College it is a great pleasure to accept this symbol which is a symbol of an honor which has been conferred and which ever will be a memory of the great pleasure which I have had and which I have much enjoyed I thank you again" (Applause)

President Bradley called upon Dr Pottenger, a member of the Nominating Committee in the absence of the Chairman of that committee, Dr Sydney R Miller, for presentation of nominees for Officers, Regents and Governors, whereupon Dr Pottenger presented the following nominations The nominations for the elective offices had been published in the ANNALS OF INTERNAL MEDICINE, official journal of the College, more than thirty days preceding, in accordance with the By-Laws

President-Elect
First Vice-President
Second Vice-President
Third Vice-President

James H Means Boston, Mass
 O H Perry Pepper, Philadelphia, Pa
 David P Barr St Louis, Mo
 Walter L Bierring, Des Moines, Iowa

BOARD OF REGENTS

Term Expiring 1939

James D Bruce, Ann Arbor, Mich
 Egerton L Crispin, Los Angeles, Calif
 James Alex Miller, New York, N Y
 Francis M Pottenger, Monrovia, Calif
 Luther F Warren, Brooklyn, N Y

Term Expiring 1938

Robert A Cooke, New York, N Y (filling vacancy of the late Charles G Jennings)
 Hugh J Morgan, Nashville, Tenn (filling unexpired term of James H Means)

BOARD OF GOVERNORS

Term Expiring 1939

Oliver C Melson, Little Rock, ARKANSAS
 Ernest H Falconer, San Francisco, CALIFORNIA (Northern)
 Fred M Smith, Iowa City, IOWA
 Joseph E Knighton, Shreveport, LOUISIANA
 Henry R Carstens, Detroit, MICHIGAN
 Edward L Tuohy, Duluth, MINNESOTA
 A Comingo Griffith, Kansas City, MISSOURI
 Robert B Kerr, Manchester, NEW HAMPSHIRE
 Clarence L Andrews, Atlantic City, NEW JERSEY
 Charles H Cocke, Asheville, NORTH CAROLINA
 Julius O Arnson, Bismarck, NORTH DAKOTA
 Alex M Burgess, Providence, RHODE ISLAND
 Kenneth M Lynch, Charleston, SOUTH CAROLINA
 Paul K French, Burlington, VERMONT
 J Morrison Hutcheson, Richmond, VIRGINIA
 Charles E Watts, Seattle, WASHINGTON
 Walter E Vest, Huntington, WEST VIRGINIA
 D Sclater Lewis, Montreal, QUEBEC

Term Expiring 1937

Walter W Palmer, New York, NEW YORK (Eastern) (To fill unexpired term of Robert A Cooke)

Upon motion by Dr Meakins, seconded by Dr Musser and unanimously carried, the nominees presented by the Committee were regularly elected

President Bradley at this point expressed his appreciation of the manner in which Dr James Alex Miller had conducted the office as President during the past year, the way the College had been run and the kindness of the retiring President for his advice Dr Bradley expressed his keen approval of the plan of having a man serve one year as President-Elect, so that he may become more familiar with the needs of the College and the means of accomplishing those needs before he is inducted to the presidency He asked for suggestions from members at large, from the Governors, the Regents and other Officers, during the year

On motion by Dr Pincoffs, seconded by several and unanimously adopted by a standing vote, it was

RESOLVED, that the American College of Physicians express its deep appreciation to all local agencies, including the Wayne County Medical Society, local committees, the local profession, the Convention Bureau, the Book-Cadillac Hotel, the committees at Ann Arbor

and the University of Michigan for their aid and cooperation in the conduct of its Twentieth Annual Session

Adjournment

Attest E R Loveland,
Executive Secretary

MINUTES OF THE BOARD OF GOVERNORS

DETROIT, MICH

March 2, 1936

The first meeting of the Board of Governors of the American College of Physicians, held in connection with the Twentieth Annual Session, Detroit, Mich., was called to order at 5 25 p m, March 2, 1936, at the Book-Cadillac Hotel

In the temporary absence of the Chairman, Dr Charles H Cocke, Dr C W Dowden acted as Chairman pro tem The Executive Secretary called the roll, with the following present Dr Oliver C Melson, Dr Tom Bentley Throckmorton, Dr Joseph E Knighton, Dr James D Bruce, Dr Edward L Tuohy, Dr A Comingo Griffith, Dr Clarence L Andrews, Dr Julius O Arnson, Dr Alexander M Burgess, Dr J Morrison Hutcheson, Dr Charles E Watts, Dr Walter E Vest (representing Dr John N Simpson), Dr D Sclater Lewis, Dr Fred W Wilkerson, Dr Turner Z Cason, Dr Glenville Giddings, Dr C W Dowden, Dr Edwin H Gehring, Dr Louis H Fligman, Dr Robert A Cooke, Dr A B Brower, Dr T Homer Coffen, Dr Charles T Stone, Dr Ramon M Suarez, Dr James F Churchill, Dr Gerald B Webb, Dr Wallace M Yater, Dr Ernest E Laubaugh, Dr Cecil Jack (representing Dr Samuel E Munson), Dr Robert M Moore, Dr Thomas Tallman Holt, Dr Allen A Jones, Dr Leila Andrews (representing Dr Leander A Riely), and Dr Louis E Viko

Mr Loveland then read abstracted Minutes of the last meeting of the Board of Governors, which, upon resolution, were approved as read

Dr Walter L Bierring, Chairman of the Committee on the Certification of Internists (American Board of Internal Medicine) distributed copies of the articles of incorporation, the Constitution and By-Laws of the proposed American Board of Internal Medicine, and discussed at length the proposed organization of this board The details of the discussion are not repeated here, since they are duplicated in the Minutes of the Board of Regents

Dr Dowden called upon the Executive Secretary to present communications Aside from those from Governors who were unable to be present, Mr Loveland read ore from Dr Adolph Sachs, Governor for Nebraska, in which Dr Sachs suggested the desirability of changing the method of electing Governors The present By-Laws provide that a Nominating Committee appointed by the President shall, after consultation with members in the various States to be represented, prepare a slate of nominees for the Board of Governors Dr Sachs' recommendation was that Governors shall be elected by their local constituents

On motion by Dr Vest, seconded by Dr Giddings and regularly carried, it was

RESOLVED, that the Chairman shall appoint a Committee to investigate the proposal of Dr Sachs concerning the election of Governors and report back at the next meeting of the Board

Dr Dowden requested from the Executive Secretary a report on the elections to Fellowship and Associateship that had been made March first by the Board of Regents Mr Loveland reported that the list of elections had been posted on the Bulletin Board and that it included the full list of candidates elected both to Fellowship and to Associateship He offered to read the names to any who had not examined the list on the Bulletin Board

On motion by Dr Griffith, seconded by Dr Melson, and regularly carried, it was

RESOLVED, that the list of candidates, both for Fellowship and Associateship, as elected by the Board of Regents, be approved by the Board of Governors

The Executive Secretary, Mr Loveland, then reported upon the names of members who had been dropped from the roster for various reasons, including failure to take up membership within one year after election

At this point, Dr Charles H Cocke, Chairman of the Board of Governors assumed the Chair

Mr Loveland proceeded with his report, distributing to members a list of those Fellows and Associates from each State who were subject to being dropped because of more than two years' delinquency He also distributed an outline of the Associates elected at the 1931 Session whose names were being dropped for failure to qualify for Fellowship The Governors were asked to take the lists with them for future reference Mr Loveland pointed out that out of a membership of something over 3300 only 16 were dropped for delinquency, a very gratifying record Members of the Board of Governors were requested to make any suggestions concerning any names on the list, with the understanding that the Board of Regents would be glad to do anything reasonable if any mistakes had been made in dropping any of the members

Dr Cocke, as Chairman, thanked the Board cordially for their cooperation and for the very excellent attendance at this meeting, for the faithfulness with which they have done their work, and particularly for their care in responding to his various communications Dr Cocke reported that since the last meeting, the College had lost through death one Master, 32 Fellows and 6 Associates He also read the list of new Life Members added since January 1, 1936, including the following

Lewis Beals Bates, Ancon, C Z
Casper H Benson, Columbus, Ohio
Donald Gregg, Wellesley, Mass
James Rae Arneill, Denver, Colo
Thomas Fitz-Hugh, Jr, Philadelphia, Pa
C Charles Burlingame, Hartford, Conn
Noble Wiley Jones, Portland, Ore
Cecil M Jack, Decatur, Ill
Anna Weld, Rockford, Ill
Roy M Van Wart, Descanso, Calif (formerly of New Orleans)
Estes Nichols, Portland, Maine
William Henry Watters, Coconut Grove, Miami, Fla

Dr Cason, Governor for Florida, presented the matter of the time of the Annual Meeting He had been requested by several of the members in Florida to present a resolution asking for the postponement in the date of the Annual Meetings to a later time in the year Dr Cason had had communications from practically every member in Florida Some of them were unable to come because of the press of work, this being the busiest time of their season Furthermore, the character of the winter in the North in March was such as not to attract members from the warmer climates

Chairman Cocke explained that the date of the meeting is usually set by the local committee on arrangements in accordance with the necessities of their local conditions, schools, hospitals, etc He offered to entertain a motion, however, for presentation to the Board of Regents

On motion by Dr Cason, seconded by Dr Churchill, and regularly carried, it was

RESOLVED, that the Board of Governors recommend to the Board of Regents and such other Officers as may be concerned in the selection of the time for the Annual Meeting to hold future Annual Sessions at as late a date in April as consistent with the convenience of those in the city in which the meeting will be held

At this point Chairman Cocke brought up the question of alternates for members of the

Board of Governors who may be unable to be present at the annual meetings. The By-Laws make no provisions. The matter had already been brought to the attention of the Board of Regents on the previous day, and that Board had given authority to the Board of Governors, as they see fit, to accept the proxies of absent Governors who were unable to attend this particular Session, and to accept their substitutes to act in their full stead and to enjoy all their full rights under the Constitution. For this reason, Dr Walter E Vest, of West Virginia, was acting in the stead of Dr John N Simpson, Dr Cecil Jack, from Southern Illinois, was acting in the stead of Dr Samuel E Munson, and Dr Leila Andrews, of Oklahoma, was acting in the stead of Dr Leander A Riely.

On motion by Dr Dowden, seconded by Dr Cason, and regularly carried, the seating of the above alternates was approved.

On motion by Dr Griffith, seconded by Dr Giddings, and regularly carried, it was

RESOLVED, that the Board of Governors suggest to the Board of Regents the desirability of having the By-Laws amended to provide for the appointment of alternates for Governors who cannot attend the Annual Sessions.

Chairman Cocke then read a communication from Dr Henry M Thomas, Jr, Governor for Maryland, discussing the ultimate future of the College, and suggesting ways and means of approaching the chiefs of various important medical services concerning promising younger members of their staffs for Associateship.

Chairman Cocke pointed out that as soon as the American Board of Internal Medicine begins to operate, there may be certain changes necessary in the way candidates may become Fellows of the College. At present, except in very exceptional cases, new candidates must be presented first for Associateship. After the new Board is operating and a physician is certified as an internist by that Board, it will form the ground work or the foundation or the presumption of his eligibility for admission to this College, although there will be several other requirements.

Chairman Cocke asked for suggestions or ideas which he might transmit to the Board of Regents for their consideration.

Chairman Cocke proceeded to the matter of the reinstatement of old members, reporting upon two cases that had been liberally discussed by the Board of Regents the day before. If a man voluntarily resigns and is out of the College for a given period of time, it matters not whether it is a year or ten years, the Regents are disposed to require him to come back either through the regular channel of reelection or on the recommendation of the Governor for his district and the payment of all past dues. Members having voluntarily eliminated themselves by resignation do so on their own responsibility, and the College should not waive their requirements and allow a man the privilege of resigning and coming back at will. Such action would create a hopeless situation with men dropping and taking up their memberships constantly.

Dr Holt, Governor for Kansas, inquired concerning the effect of new changes that would be brought about by the operation of the American Board of Internal Medicine.

Chairman Cocke informed the Board that until the Constitution and By-Laws have been amended candidates will continue to come in under the present arrangement. It is quite certain, however, that amendments will be adopted as soon as the Board is ready to operate, and that thereafter new candidates will be subject to the new requirements.

Dr Burgess, Governor for Rhode Island, wished further discussion of the matter of reinstatement of members, presenting an illustrative case of a member stricken with pulmonary tuberculosis, or some other illness, making it necessary for him to retire from active membership in his societies. Such a man might later recover and desire to be reinstated.

Chairman Cocke replied that there was no need for such a man resigning, that the By-Laws provide that in the case of protracted illness and retirement from practice, a member is entitled to appeal to the Board of Regents for a waiver of his dues during such period. The Board of Regents, in accordance with the By-Laws, are considerate in such cases and, hence, no member needs to sacrifice his fellowship in the College because of his health. Upon a member's recovery and resumption of practice, his status changes to that of a paying

member, and in the meantime there is no necessity for reinstatement because he has remained a member all the time

Dr Moore, Governor for Indiana, reported on College membership in his State. In that State it has appeared difficult to procure men who are doing wholly Internal Medicine in any given smaller city. Many of the men in these cities who would be interested in the College, however, do restrict their work to 90 per cent or 95 per cent Internal Medicine. However, some of these are doing, to some degree, minor surgery and handling an occasional obstetrical case. Many of these men are interested in College membership, though the question has existed as to whether they are qualified under the circumstances.

Chairman Cocke suggested to Governor Moore that such men might properly be proposed for an Associateship. Candidates limiting their work almost wholly to Internal Medicine may be considered eligible for Associateship, with the understanding that before they come up for Fellowship they will probably be able to limit their work wholly.

Chairman Cocke then informed the Board of Governors concerning the details of the discussion in the Board of Regents concerning the procuring of a College Headquarters or permanent home. Quoting from his remarks: "The headquarters is located in a singularly small and inadequate suite of offices at 36th and Walnut Streets in Philadelphia. During the incumbency of Mr Loveland as Executive Secretary, the funds of the College have increased remarkably, namely, from approximately \$9,000 to \$158,000. It has been the thought of many of the Regents that since this fund has been raised without specific, definite, planned ideas for its distribution, or its use, although the College has used a certain amount for awards, for scholarships and that sort of thing, and while the College will continue to foster those projects, the time has arisen when the College must have more adequate, better and larger facilities, through the building or acquisition of a suitable home. Those who were present at the Regents-Governors Banquet last evening, March first, heard the discussion presented so well by Dr Alfred Stengel, Chairman of the Temporary Committee appointed to look into the feasibility of this project. I would be very happy to have any reaction or any remarks from any Governor present as to his feeling or thoughts of his constituents toward this possibility. Of course, a natural corollary of that would be that there would be some reduction either of the dues, or, more particularly, of the initiation fee once a permanent home has been acquired."

Dr Yater, Governor for the District of Columbia: "Mr Chairman, certainly there is no question as to the advisability or the necessity of such a permanent headquarters. It is perfectly ridiculous that such an organization as this should not have had one long since. Furthermore, with all the troubles brewing in our country at the present time and the possibilities of inflation, and what not, if we wait, say a year or so, to feel out the consensus of opinion of the majority of our members, we shall be losing very valuable time and money, because a year from now very likely the property which we can now obtain for a certain figure will probably cost much more and construction will be more expensive. This would seem to me also to be a very important consideration in the investment of our funds. In order to bring the matter to a point of discussion, I would move, Mr Chairman, that the Board of Governors shall express to the Board of Regents their approval of the project for the acquisition of a permanent College home and headquarters, and, further, that the Board of Regents proceed immediately on the project."

The motion was seconded by Dr Griffith, Governor for Missouri.

Dr Bruce, Governor for Michigan: "I can't resist the temptation to tell you all how gratified I have been personally and how gratified the members of Michigan have been with the progress of the College, and I am perfectly sure that I am expressing their wishes in supporting the motion that has been made. They will be very happy if this can be carried through."

Dr Tuohy, Governor for Minnesota: "I am glad to voice the opposition and to elaborate on what I have already said. I think it is quite obvious that you are going to have this building, but I shall appreciate, nevertheless, if you will bear patiently with me for a moment while I attempt to clarify my position. I believe the American College of Surgeons has

added nothing to the prestige of that organization, or to the advancement of the purposes for which they were originally established, by the acquirement of their home. I want to clarify the matter as to the centralization in Philadelphia. I think the advisability of that has been well proved by the success that has come to the College since the work was centralized, and so I think there is, in fact, no argument pertaining to that feature. Philadelphia is a happy choice, both from the standpoint of traditions of medicine and the first hospital and the first medical school established in the United States. If the College Headquarters were developed in Washington, near the Surgeon General's Library, I think the advantages would be of little moment in comparison to the equal advantages that exist in Philadelphia."

Dr Tuohy proceeded to ask for a consideration purely on a business basis, and pointed out that the College funds could be invested in other than United States securities, if inflation is threatened. He recommended careful consideration of renting more space in Philadelphia as a comparison with the cost of maintaining a College Headquarters. He questioned whether a College home would be considered by the members at large of any value. He recommended various methods of extending the sphere of influence in the College into various sections of our country, including regional convocations with the purpose of instilling better Internal Medicine into the various States and Provinces. He further pointed out that the Royal College of Physicians has given little attention to its housing. He urged no hasty action until the matter had been duly considered.

Dr Holt, Governor for Kansas, also spoke to the question, and Dr Cason, Governor for Florida, insisted on some word from the Executive Secretary from the standpoint of a business man who may thoroughly understand the facts of the case, because of his closeness to the College.

Chairman Cocke replied that the progress thus far had been carried on not only with the advice and cooperation, but with a very active interest of the Executive Secretary, but that the Executive Secretary had expressed a preference not to enter too actively in the discussion of the matter. However, he called upon Mr Loveland to make some remarks to the inquiries.

Mr Loveland pointed out, first, that the matter of the College Headquarters is one to be settled by the College. A committee had been formed which had called upon the Executive Secretary to determine certain information and to make certain surveys, report on which had been presented by Dr Stengel. He said he was favorable to the project, second, the College by conservative operation and care has accumulated a considerable surplus, which is likely to be dissipated with an increasing interest in other projects and probably through changing personnel on the various Boards. The By-Laws provide for a certain amount of change in members of the Boards, and without disparaging the good intent of any one, the investment of a certain part of the surplus in some worthy problem, such as an appropriate and dignified home for the College would be a safeguard. However, the chief consideration was the actual need of larger and more adequate quarters. Many members of the College visit the College Offices every year and frequently express disappointment in the rather small and inadequate quarters. The efficiency of the College work is somewhat hampered by inadequate facilities. He said he would not recommend an extravagant building, but something fairly modest, of attractive architecture and of reasonable proportions for present and future work of the College. In his opinion a permanent headquarters would contribute toward stability. These surplus funds might readily be used, if not for a College Headquarters, for other purposes that may be far less enduring. Adequate quarters would make it possible for members of the College to come to Philadelphia and use them for their headquarters, where mail could be sent, consultations held, and so on. The College, further, could operate better with its members in arranging programs to see what is being done medically in Philadelphia, or for postgraduate study. The headquarters might also be used for the giving of examinations by the American Board of Internal Medicine, after its formation. It is also possible that some other medical group or groups might use, on rental from the College, any excess space available for their own offices.

Dr Griffith, Governor for Missouri: "I want to go on record as saying that I am for

this proposal all the way through I do not think the American College of Surgeons and the American College of Physicians should be compared. One is a huge organization with many members and different branches all over the country. Ours is a real fellowship organization. We have a smaller, more limited number of members. I think we are an organization that should have a permanent home, a place to which we can point with pride. I am not in favor of Washington. That location would be all right if we were a larger political organization and wanted to get something out of the Government. As to inflation, whether we have stocks or bonds, we are drawing a certain interest from our money. The dollar is now worth only fifty-nine cents, and if we have further inflation, no one knows what its worth will be. If we have real property, we shall have something tangible, and the value will be there."

Dr. Suarez, Governor for Puerto Rico: "This is the first meeting of the Board of Governors that I have attended, and I have been most favorably impressed by the things I have heard. It took me six days to get to this meeting, and I cannot resist the temptation to say at least a few words about the building of a permanent home for the College. I have been President of the Puerto Rico Medical Society for three years, and during my incumbency, a beautiful home for the medical profession of the Island has been built. We are proud of it and we think it is one of the best things we could have done for the medical profession there. I frankly and firmly believe that the construction of a permanent home for the American College of Physicians would be a most definite sign of permanency and stability, and I see no reason why, since we have progressed so wonderfully since our headquarters were established in Philadelphia, the new building shouldn't be constructed also in that City."

Dr. Giddings, Governor for Georgia: "It seems to me that it is practically essential for this College to have a headquarters. Certainly if this examination and certification of internists is passed and put into operation, the necessity of such a headquarters will be even greater. I rather feel that we not only should have a home, but that the place should be fireproof, and I rather question whether such a structure can be erected for the sum that has been suggested."

Dr. Moore, Governor for Indiana: "I want to be on record as for this project. I feel favorable toward establishing a permanent home. As to other projects of the College, I am well acquainted with fellowships. I have observed many fellowships established to help students through school. It doesn't make a bit of difference whether it is a fellowship from the American College of Physicians or some other organization. Most of the money spent on these fellowships is soon gone and forever forgotten. If we have something substantial to which we can point, I think it will bring prestige to our organization, as it should. It doesn't make any difference whether it is your own office or the headquarters of your organization. If you have a poor office, it doesn't impress your visitors favorably. An organization of our standing and our honor, I think, can have nothing but the best."

Chairman Cocke put the motion to a vote, whereupon the resolution was unanimously adopted.

RESOLVED, that the Board of Governors shall express to the Board of Regents their approval of the project for the acquisition of a permanent College home and headquarters, and, further, that the Board of Regents proceed immediately on the project.

At this point, Chairman Cocke introduced the President of the College, Dr. James Alex. Miller. (Applause)

President Miller: "It is particularly a pleasure to be here and to get the reaction of the Board of Governors on this conception which has arisen in the Board of Regents, and I can tell you that your reaction taken this afternoon will have very great weight in determining the action of the College through the Board of Regents, where, of course, the responsibility lies. I also want to say that at our meeting last night, it was a great pleasure to us of the Board of Regents to be your hosts. That dinner was not a College affair, but was a spontaneous and personal invitation on the part of the members of the Board of Regents to the members of the Board of Governors, expressing the personal anxiety of the former to get

closer to the Governors That was the basis on which that meeting was held, and which I hope will be a precedent for similar meetings I also want to say that during this last year, over which it has been my privilege to preside as your President, I have been more and more impressed with the importance of the Board of Governors individually and collectively in the affairs of this College Of course, we have our Constitution and By-Laws, certain prerogatives, certain details and privileges are assigned to the Board of Regents and others to the Board of Governors, but we are all cognizant that it is the personnel of the College which counts, and it is there that the Board of Governors must take the initiative I feel so strongly about this that I have made it the practice during the last two or three years not to exercise as Regent my prerogative to certify or to endorse candidates I think that under certain exceptional circumstances, perhaps, it is wise to allow a Regent to endorse a candidate, but I have made it an invariable rule when proposals have been sent to me to refer them to the Governor of my district, in order that they may go through the regular channels of the Board of Governors, because I believe the responsibilities should rest with them, and I believe it is up to you, gentlemen, to exercise as you have in the past, but even increasingly in the future, a good deal more of a sense of responsibility in passing upon the credentials of candidates whose proposals you pass to the Committee on Credentials It is not fair or right to send a doubtful candidate's proposal to the Credentials Committee, you usually have available first-hand information, whereas that Committee does not, and if they do not receive it, they cannot act in the best interests of the College

"I also think that you should insist more and more upon discretion on the part of Fellows who present candidates to be endorsed by you We must have greater local autonomy, or at least a greater local sense of responsibility toward the problems of the College

"I, too, feel as you, gentlemen, have expressed it, that we will go far, if we have our permanent home, toward increasing the feeling of pride and stability in our organization, which I think is extremely important An even more important step is that which we are making on the question of the certification of internists, which, when it is consummated, will make it quite possible for us to use that examination instead of the preliminary stage of Associateship That is not yet an assured fact, but is being considered in that connection You should understand that it is not the idea of the present Board of Regents that this certification will in any sense qualify an individual for Fellowship It will simply give him the basic minimum requirement, and in the future, I hope, no one who is not certified as an internist will be even considered by our Credentials Committee After that, we can add any particular requirement and essentials that we think wise I feel sure we are just ready for a move forward for this organization which is going to make it a great power, not only from the standpoint of the standards of practice, but also in the standards of qualification for certain types of practitioners, specialists, if you want to call them such I hope we shall also have an opportunity to exercise great influence on ethical standards, which are tremendously necessary I think we may be very proud of the leading part that the College has taken in this matter Thank you very much for the privilege of speaking to you" (Applause)

On motion by Dr Griffith, seconded by Dr Yater, and adopted by a unanimous rising vote, it was

RESOLVED, that the Board of Governors express to the members of the Board of Regents their keen appreciation and thanks for the Dinner tendered them on March 1

Executive Secretary

MINUTES OF THE BOARD OF GOVERNORS

DETROIT, MICH

March 5, 1936

The second meeting of the Board of Governors of the American College of Physicians, during the Twentieth Annual Session, was held Thursday, March 5, at the Book-Cadillac Hotel, with Dr Charles H Cocke, Chairman, presiding, and with the following present Dr Oliver C Melson, Dr Tom Bentley Throckmorton, Dr Joseph E Knighton, Dr James D Bruce, Dr Edward L Tuohy, Dr A Comingo Griffith, Dr Clarence L Andrews, Dr Charles H Cocke, Dr Alexander M Burgess, Dr J Morrison Hutcheson, Dr Walter E Vest (representing Dr John N Simpson), Dr D Sclater Lewis, Dr Fred W Wilkerson, Dr Turner Z Cason, Dr Glenville Giddings, Dr C W Dowden, Dr Edwin W Gehring, Dr G W F Rembert, Dr Louis H Fligman, Dr A B Brower, Dr T Homer Coffen, Dr Charles T Stone, Dr James F Churchill, Dr Gerald B Webb, Dr Henry F Stoll, Dr Wallace M Yater, Dr Ernest E Laubaugh, Dr Cecil Jack (representing Dr Samuel E Munson), Dr Robert M Moore, Dr Leila Andrews (representing Dr Leander A Riely), Dr Louis E Viko and Dr Jabez Elliott, and E R Loveland, Executive Secretary, acting as secretary of the meeting

By resolution, the reading of the Minutes of the previous meeting was dispensed with

Chairman Cocke reported to the Board upon matters he had been instructed to refer to the Board at a previous meeting

(1) The resolution urging the Board of Regents to proceed toward the acquisition of a College Headquarters was favorably received and spread upon their Minutes

A new committee was appointed by the President to take the matter in hand, with instructions to bring in definite and concrete specifications as to location, type of building, etc, at the next meeting

(2) The resolution containing recommendation for amendments to the By-Laws providing for appointment of alternates for Governors who cannot attend the Annual Sessions was approved, and the Committee on Constitution and By-Laws instructed to draw up proper amendments

(3) The resolution requesting a later date for the Annual Sessions was received and given due consideration, with the result that the 1937 meeting will be held later in the year than customary

At this point, Chairman Cocke called upon a special committee previously appointed to consider the suggestions of Dr Adolph Sachs, Governor for Nebraska, for a new method for election of Governors The following report was received

"The Committee appointed by you to consider the suggestions made by Dr Adolph Sachs, Governor for Nebraska, namely, 'that in the future the Governor for each State shall be elected by the Fellows in his respective State or district,' met Wednesday afternoon, March 4, 1936, and, after due deliberation, unanimously recommends that there be no change in the present method as provided in the By-Laws, for the following reasons

"First, under the present efficient method carried out under the By-Laws, the College has advanced and thrived without any type of dissension

"Second, your Committee is quite fearful that if the election of Governors be left to the decision of Fellows in the respective States, politics might readily enter

"Respectfully submitted,

C L ANDREWS,

F W WILKERSON,

A C GRIFFITH, *Chairman*"

On motion by Dr Knighton, seconded by Dr Yater, and regularly carried, it was RESOLVED, that the Board of Governors adopt the above report

Chairman Cocke reported that while the final amendment would specify the method of appointing alternates, it was his understanding that the power of appointing an alternate would be vested in the local Governor, who should certify to the Executive Secretary the appointment of his alternate, and should give a letter of appointment to the alternate himself

The Executive Secretary, Mr Loveland, distributed copies of the financial report of the College for 1936 He reminded the Governors that while the Board of Regents is responsible for the business operation of the College, it is desired to keep the Governors also informed He reminded them that the accounts of the College are audited each year by a certified public accountant He reviewed the various parts of the report, summarized the operating statements and explained the General and Endowment Funds The financial reports have been published in connection with the Minutes of the Board of Regents, and are not here repeated There was general discussion about the various statements, and a keen interest displayed by members of the Board

Dr Throckmorton, Governor for Iowa, called attention of the Board of Governors to the income from the annual exhibits, as shown in the statement He stated that that was one of the first things which struck his attention, because of his own experience with exhibit work in his State society and in some national organizations He pointed out that the success of these exhibits represents an unusual amount of work carried on by the Executive Offices, and it should be deeply appreciated by the College He added, "I know from personal experience that it takes a lot of good hard work not only to get exhibitors, but after having gotten them to keep them satisfied and to keep them coming, and for that reason I personally want to compliment the Executive Secretary and his staff upon that unusual work which they have done in this particular line It shows in the income that it is a mighty fine thing for the College I would call your attention to the fact that this activity accounts for a considerable part of the surplus which may be used for the acquiring of a College home and other activities I want to say that this surplus came largely from the sweat of the brows of the Executive Secretary, the Finance Committee and the Regents, and there is nothing unworthy about it at all"

Chairman Cocke pointed out that the commercial exhibits before the College meetings are carefully censored, and an earnest effort is made to admit only the most ethical and reliable products

Dr Vest reported that his examination of the exhibits had shown that nothing in the exhibit was worthy of criticism in any way They were all proper exhibits

The Executive Secretary then reported upon the publication, during the autumn of 1935, of a new Directory of the College He called attention to the revised arrangement of data, and expressed the hope that the usefulness of the Directory would be greatly extended Mr Loveland further reported on the new Life Members of the College, totalling now 61 in all, he reported on the elections to Fellowship and Associateship and gave the membership statistics By resolution, the report of the Executive Secretary was accepted

The Executive Secretary presented for the advice of the Board of Governors the problem of whether or not there should be published in the Directory the names of all Associates as well as the Fellows, as done at the present time As a matter of fact, Fellows and Masters only are "members" in the true sense of the word, since Associates do not have the power to vote, nor is the Associate roster a permanent one Associates of the College in general may be divided into three groups (a) those who first entered as members of the American Congress on Internal Medicine and were automatically given the status of Associates when the said Congress was merged with the College in 1926, (b) men elected to Associateship after meeting definite requirements for the same between 1926 and 1929, (c) Associates elected since 1929 who are under obligation to qualify for Fellowship within a maximum period of five years from election to Associateship The first two groups may remain Associates indefinitely, because the amendment to the By-Laws requiring qualification

for Fellowship by Associates only began to apply in 1929. Suggestions had been received in the College office that possibly the official Directory of the College, upon which members of the College are judged, should include only full-fledged Fellows.

Chairman Cocke requested a discussion of the matter.

Dr. Bruce, Governor for Michigan, after discussing the matter, summarized his opinions by saying that he felt we are perfectly able to vouch for all the Associates who have been elected since 1929, because they were compelled to meet certain definite requirements, and unless they succeed in qualifying for Fellowship, their names automatically will be dropped. For the earlier group of Associates who were brought into the College automatically, he felt some provision should be made so that they could be distinguished from the rest of the Associates.

On inquiry from Dr. Dowden, Governor for Kentucky, it was brought out that the American Medical Association in its Directory does not recognize as members of the College others than Masters and Fellows. Dr. Dowden expressed the opinion that Associates might be omitted from the Directory, so that confusion of Associates as full-fledged members might be obviated.

Dr. Knighton, Governor for Louisiana, expressed his gratitude for having the various classes of Associates clearly defined. He continued to report upon a sectional meeting of the Fellows and Associates of the College in the form of a combined clinical and social meeting in Shreveport during January, 1936. The membership especially represented was that of northern Louisiana. Dr. Knighton reported a very successful meeting with full attendance, lacking two, in that entire territory, and with additional meetings planned for the future.

Returning to the matter of the College Directory, Governor Griffith suggested that Associates of the College granted by virtue of membership in the old American Congress on Internal Medicine should be published separately, or under special designation.

Dr. Jabez H. Elliott, Governor for Ontario, concurred in this suggestion. Dr. Elliott said that it should be a question for discussion whether the College should carry the Associates in the Directory at all, because of the confusion in the minds of certain people as to whether or not they are full members of the College. However, if the Associates shall be published, then those who were admitted previous to the establishment of definite admission requirements should be set apart.

Chairman Cocke pointed out the condition should be corrected in the next Directory, but inasmuch as the next Directory will not be published until 1937, the intervening time might be used for more mature thought and for definite action at the next meeting. Dr. Cocke suggested that perhaps one of the means of handling this situation would be to have a full official Fellowship Directory of the College and to issue a supplementary Directory of Associates. The official Fellowship Directory would be the one distributed to libraries, medical schools and other official institutions.

Dr. Vest suggested that in our Directory we should publish only the Fellows and a list of "eligibles." This eligible list would include only those who are eligible for advancement to Fellowship, and would eliminate the names of all those who have not met the preliminary requirements for Fellowship.

President Bradley, at the request of Dr. Churchill, explained that the American Congress on Internal Medicine and the American College of Physicians were founded as two separate organizations. The first essential to be a member of the American Congress on Internal Medicine was merely a desire to attend its meetings and to pay an admission fee of \$5.00. There were always requirements for admission to the College. However, the meetings of the College and Congress were held together, and members of the College were recruited more or less from members of the Congress. When the Congress was discontinued, its members were accorded Associateship in the American College of Physicians.

Dr. Brower, Governor for Ohio, inquired how many such Associates still remain on the list and what is their average age. An examination of the list by the Executive Secretary

indicated there are 173, whose average age is 57 years. Ten of these are 65 years of age or older, and, therefore, on the dues-waived list. The balance pay the regular Associateship dues.

Dr Moore, Governor for Indiana, and Chairman Cocke both concurred in the opinion that this Directory is being used by hundreds of physicians who are not members and by hosts of physicians who do not attend the Sessions of the College. It is not infrequently that the Directory is used for reference for physicians to whom patients may be referred because of the removal of such patients from one part of the country to another, or because of travel. They expressed the opinion that the Directory should contain only the names of physicians whose credentials are of high grade.

Dr Andrews, Governor for New Jersey, expressed the opinion that the College is under some obligation to this earlier group of Associates, because of the original agreement to grant them Associateships.

Dr Hutcheson, Governor for Virginia, suggested that Fellows be given complete geographic and alphabetical listing, but Associates be listed alphabetically only in the back section of the Directory.

Dr Holt, Governor for Kansas, expressed the opinion that the obligation of the College to these early Associates is such that their regular listing should be maintained.

Dr Ernest B Bradley, President-Elect of the College at this juncture was called upon to address the Board of Governors briefly, asking them for their suggestions, aid and cooperation during the coming year, the term of his Presidency.

Chairman Cocke opened a discussion of regional or State meetings of members of the College. He expressed the opinion that the objects of these are (1) the establishment of greater coherence among the Fellows, (2) building up of more local pride in Fellowship, (3) dissemination of a better understanding of what the ideals and purposes of the College are, and (4) the furtherance of wider acquaintanceship and better fellowship among the members.

Dr Cocke reported that during the past year he had attended two of the State meetings, one in Kentucky and one in his own State of North Carolina. He had had reports from several Governors who had conducted such meetings in their territories. These meetings should be conducted by the Governor, and in some instances may be joint meetings among two or three neighboring States where the membership is smaller and the cities not too far removed from one another.

Dr Griffith, Governor for Missouri, announced that during the meeting of the American Medical Association in Kansas City during May some attempt will be made toward having a social meeting of members of the College from that community. He extended a cordial invitation to all members of the Board of Governors, Board of Regents and members of the College to be there.

Dr Yater, Governor for the District of Columbia, recommended that the College office should maintain up-to-date records about all of the members of the College, new honors, new positions, new publications, etc. He said there should be some one place in the country where internists shall have available a complete up-to-minute record of the medical histories of the outstanding men. Each year a form could be sent out by the Executive Secretary to all of the Associates and Fellows, probably more importantly to the Associates, asking them to put down changes in their status in their respective communities, new positions they are holding, outline of articles they have written, outline of papers they have delivered before national organizations, etc. This might also be quite a stimulus to Associates who must prepare their credentials for Fellowship by inquiring each year what they have accomplished during the preceding year. They will be reminded and given a stimulus toward better qualifying themselves for Fellowship.

On motion by Dr Yater, seconded by Dr Andrews, and regularly carried, it was

RESOLVED, that the Board of Governors suggest to the Board of Regents that each year the Executive Secretary send out appropriate questionnaires to obtain information as to the

status and work that members of the College have done during the preceding year, and that these records shall be kept on file in the headquarters office

On motion by Dr Giddings, seconded by Dr Yater, and regularly carried, it was

RESOLVED, that the Board of Governors draw up resolutions expressing its very deep sympathy for the family of Dr Charles G Jennings and also for the family of Dr Frederick Epplen (Secretary's note Dr Charles G Jennings, deceased, was General Chairman of the Twentieth Annual Session at Detroit, 1936, a Master of the College, and for many years Chairman of the Board of Governors, Dr Frederick Epplen, deceased, was for many years Governor for the State of Washington)

Dr Andrews, Governor for New Jersey, expressed his disappointment that the Daily Bulletin had been discontinued at the current Session. He expressed the opinion that many other members were likewise disappointed. It served as an aid in locating members of the College who were in attendance at the meeting and as a guide to the happenings of the current day.

The Executive Secretary, Mr Loveland, explained that the Daily Bulletin had been discontinued primarily because of the expense of publication and the amount of work entailed. The Daily Bulletin had to be printed at night. The burden fell upon the Executive Secretary's office because there was no one else available to edit the Bulletin. It had been initiated unofficially by him a few years back for the sake of aiding the exhibitors whose daily write-ups appeared therein, in addition to the outline of committee meetings, registrations, etc. On one occasion he had sought the Editor of the ANNALS OF INTERNAL MEDICINE to act as Editor of the Daily Bulletin, but the Editor had not found it possible to take on this added duty. Exhibitors had expressed the opinion that the Daily Bulletin was of little or no value to them, provided the Executive Offices would furnish them with lists of the registration at the end of the meeting. There had been very few comments of the members indicating appreciation of the Bulletin, and, therefore, because of the cost and tremendous amount of work connected with its daily appearance, it had been discontinued. Mr Loveland, however, explained his willingness to place the matter before the Board of Regents and to continue its publication if so authorized.

Dr Churchill, Governor for southern California, reported that he too had heard many remarks expressing disappointment about the discontinuance of the Daily Bulletin at the Detroit meeting. He said that he himself had missed it because being one who has some difficulty in associating names and faces, the Bulletin has been a great aid in identifying those present.

Dr Cason, Governor for Florida, suggested that the College keep the situation in Havana, Cuba, open as a possibility for taking some of the men into the College membership. Some years ago the Board authorized him to keep the situation in mind, and he has continued his contacts, but conditions have been so chaotic that no steps have been taken.

ANNALS OF INTERNAL MEDICINE

VOLUME 10

AUGUST, 1936

NUMBER 2

THE PRESENT STATUS OF THE TREATMENT OF PULMONARY TUBERCULOSIS*

By LAWRASON BROWN, M D , F A C P , *Saranac Lake, N Y*

THE marked decrease in the mortality of pulmonary tuberculosis is undoubtedly due to many causes. It is not, many hold, a true measure of the decrease of the morbidity of the disease. Pulmonary tuberculosis is still a very menacing cause of death to both sexes during the period of greatest bodily and mental activity. The keen desire for a cure for tuberculosis, a true *therapia magna sterilisans*, so widely spread at the beginning of the century, is now less evident. Some foundations and laboratories consider tuberculosis an unpromising field of endeavor and have left it largely to the clinicians and sanitarians, who have contributed much. Few will question that more efficient treatment is one of the causes of the decreased mortality. Such treatment acts in two ways: it frees the sputum of tubercle bacilli and aids the victims to arrest really and permanently their disease or to live long enough to die of other causes.

To assess the value of different methods of treatment in any chronic disease is far from simple. The faith of him who introduces a new measure is too often passed on to him who receives it. Several years ago I spoke to some members of this College of the influence of the mental aspects upon the results of the treatment of pulmonary tuberculosis. I attempted to show at that time what a powerful effect suggestion, applied consciously or unconsciously, played in the results of treatment. I think I recalled at that time the practice attributed to an acquaintance who, posing the tuberculin containing syringe, uttered just as he inserted the needle, the incantation, "This is the life giving fluid." Any patient to whom he had in the vernacular "sold the idea" of tuberculin responded no doubt as fully as those lulled to sleep with the words, "You are better in every way every day." Misery undoubtedly begets credulity. This is probably the explanation of why many measures for the relief of pulmonary tuberculosis are helpful in the hands that introduce them, failures in the hands of others.

We hear today on all sides how the treatment of pulmonary tuberculosis has been revolutionized since the introduction of collapse therapy. For

* Presented at the Detroit meeting of the American College of Physicians, March 6, 1936

the "far advanced" patient and for many of the progressively "moderately advanced" patients this is true. We all hail the advances made possible by the fundamental studies not only of the surgeons but also of the physicians Brauer, a physician of Marburg, and later of Hamburg, spread the idea of collapse treatment throughout Europe and even back to America after he had received the suggestion from an American surgeon. Forlanini, the father of pneumothorax, was a physician. If we really face the facts, none of us can today think of the treatment of pulmonary tuberculosis without having always before us this collapse treatment. Some of our surgical confreres almost scout the idea that pulmonary tuberculosis is anything else than a surgical disease. They would have us hurry most patients to the operating room for fear that the disease may progress too far for surgical relief. They even lead us to believe that at some stage every patient can be greatly helped by the needle or by the scalpel. After living with pulmonary tuberculosis for some 35 or 40 years I cannot accept such a statement without some reservations.

The majority of those familiar with pulmonary tuberculosis in all its stages do not hold that patients in the minimal stage require, by and large, any form of surgical treatment. Certainly the great majority have recovered without such interference, and the last word is chosen carefully. The records at the Trudeau Sanatorium reveal only 8 per cent of these "minimal" patients dead at the end of 15 years. Such patients rarely fall into the hands of the surgeons, and many surgeons are not familiar with the excellent results obtained in such patients. Indeed some surgeons speak as if patients in this early stage presented cavitation, which is entirely wrong, for cavitation places them immediately in the second or advanced group. I might go even further and state that few, very few, of these "minimal" patients, only those with definitely advancing disease after treatment by rest, exposure to fresh air, by feeding with good food, and by treatment of symptoms as they arise, require more than these simple measures. But to treat pulmonary tuberculosis successfully does necessitate familiarity with the use of these fundamental means and how to judge of their effects.

It is then extremely important to know the proper treatment of this early stage of pulmonary tuberculosis. As soon as it has been diagnosed and as soon as it is determined that the lesion is active, rigorous treatment should be instituted. Now this treatment, less empirical than it was some 35 years ago, still revolves about the triad of rest, food, and air. Experience accumulated as the years have rolled on, based upon the unfortunate outcome of the treatment of certain patients, has emphasized the fact that the knowledge of the proper use of these seemingly simple measures is not acquired in a single interview to such a degree as to lead to certain and ultimate recovery. To this end we must add to the triad the education of the patient. The fundamentals then of all successful therapy of early pulmonary tuberculosis consist of (1) rest in the beginning and properly regulated

exercise later, (2) good food, (3) fresh air, (4) and finally, to insure the permanency of the recovery, proper education of the patient

(1) Concerning rest Injury ever demands rest for repair Surely the reason for pain in the universe is not only to teach the uselessness of breaking the laws of nature but also to emphasize the value of rest Unfortunately pulmonary tuberculosis is only infrequently associated with pain and the ignorant have their fears quickly lulled into a false sense of security and of approaching well being Weakness, they argue, can be overcome by exercise Many, conscientiously and literally, have walked themselves into their graves For these reasons I invariably put all such "minimal" patients to bed for a period of at least six weeks I permit them to go to the bathroom and even certain of them to go to the table but never allow them to dress or to go up or down stairs I attempt to explain to them why the lung requires rest for recovery Later I get them out of bed very gradually, permitting them to begin exercise at the end of six weeks by walking one or two minutes twice a day, without dressing, and increasing the amount of walking by one or two minutes a day until they are walking 20 minutes twice a day Then if they have a flight of steps to navigate I start them on one step a day until they reach the bottom Not until then do they dress Following this they walk on the street at first for 10 minutes twice a day for a week, then for 20 minutes, for 30 minutes, for three-quarters of an hour and finally for an hour twice a day When they reach this stage they can seldom hurt themselves by walking on the level to which I have so far confined them The recollection of this slow progress has a very salutary effect upon their future actions My suggestion is that in proportion as you can give any organ functional rest so you can aid it to recover from tuberculosis

(2) Concerning food There has been abroad in the tuberculosis land an impression that if a little food was beneficial, an increase might be more quickly helpful This was no doubt the basis for the old saying at the Trudeau Sanatorium that a patient must eat once for himself, once for the germs, and once to gain weight You will recall that in the time of Laennec and Louis a reproach, thrown in the faces of those who advocated the early diagnosis of phthisis, was that such a diagnosis led but more surely to the grave This rebuke, uttered both in Europe and in America, had much truth in it About a decade later you will remember the London *Lancet* intimated that if Dr George Bodington continued to feed his patients such food as beefsteak he would lay himself open to prosecution for malpractice Now at this time early diagnosis of pulmonary tuberculosis was rarely made, and when made, could usually be confirmed from across the way Such emaciation demanded food in far larger quantities than is needed for the class of patients we are now discussing The amount of good food that has been wasted upon the early patients has been appalling and unfortunately upsetting The strict Gerson diet, so effective in some cases of cutaneous tuberculosis (especially lupus), is far less, if at all, helpful in pulmonary

tuberculosis For some years, in the hope of changing an exudative into a proliferative reaction, I have been using, with some encouragement, a diet high in vitamins C and D, restricting the intake of sodium chloride and giving dicalcium phosphate I would like to suggest that the least amount of food that any patient who is under weight can gain upon is the optimum diet for that patient

(3) Concerning fresh air Inflammation of the lungs, it was held years ago, demanded protection Pulmonary tuberculosis was associated with such inflammation and so required protection also Night air was bad Change in temperature was deleterious So the patient should never go out at night and the temperature of the house must be kept high and not vary Such views were as wrong as those of the *Lancet* on diet They were based on two erroneous principles first, that patients with pulmonary tuberculosis needed warm and equable climates, and second, that the only organ concerned in recovery was the lungs Today we know that fresh air affects the lungs no more, no less, than it does the knee The chief effect of aerotherapy is manifested through the skin, and a variation of 20 degrees during the 24 hours is highly desirable These early patients should have a room connected with a porch upon which the bed can be rolled If this cannot be had, there should be a bed on the porch and one in the room I am no advocate of sleeping out of doors for patients who spend hours in the open air every day During the cool and colder months I insist that the patient spend at least six or seven hours in the open, tempering the time to the vigor of the patient Such patients can recover in a room but the psychological stimulation, apart from any other factor, makes some hours on a porch most desirable I would suggest that recovery from pulmonary tuberculosis depends upon six or seven hours in the open, and on good ventilation during the remainder of the twenty-four

(4) Concerning education This should begin at the time of diagnosis Ignorance inflicts often severe and possibly fatal penalties Even when they pay a lesser price ignorance often issues to patients a pass to the surgeon whom we are now trying to avoid Further, a little knowledge is a dangerous thing, especially when passed on from one patient to whom it may apply to another to whom it may bring disaster Three months are necessary for the education of any patient The time you keep him in bed is your golden opportunity He is most anxious to learn how to avoid bed in the future Urge him to ask questions, have him write them down Treat him as an adult Give him answers for whys and wherefores Be frank but optimistic The value of a good nurse who is familiar with pulmonary tuberculosis is inestimable I would suggest that in any chronic disease like pulmonary tuberculosis the therapeutic triad will bring about arrest of the disease, but education alone will make it permanent

For patients in the minimal stage it is remarkable what these apparently simple measures, when intelligently applied, will accomplish I have already stated that among the patients discharged from the Trudeau Sanatorium

it has kept 92 per cent alive for at least 15 years. If there is any other form of treatment that produces better results I am unaware of it and am keenly desirous of hearing about it.

Furthermore, all patients with or without surgical interference, sooner or later, for a longer or shorter time, must follow such treatment. Hence the necessity for complete and accurate knowledge concerning it. Where these measures should be used is for most of these "minimal" patients of far less importance than the length of their application. The surgeons have stated that it requires little or no more time for a long than for a shorter incision to heal. Applying this to pulmonary tuberculosis I would like to emphasize that a small but definite lesion of pulmonary tuberculosis demands several years of treatment, possibly more or less modified, for a permanent arrest. Failure to recognize this and to pass it on to the patient is the most frequent cause of relapse among these early patients. Emphasize that while work may be resumed, arrest too often lingers. Tell him he may play and get well, or work and get well, but rarely can he work and play and get well.

When the patient has passed beyond this early stage the picture changes. The outlook is very different and much more serious, for the progress of the disease may now be difficult to check or such damage may already have taken place that any hope that a permanent arrest may follow the simple measures previously outlined has to be abandoned. However, granting the possibility of a successful result, so long a time is now required to bring about the desired recovery by simple means that for many it is an economic impossibility. Even for those with means the years of sacrifice of ambitions and of desires are too likely to be interspersed with periods of lapses from the straight and narrow path of tuberculosis rectitude which may lead the wanderer into the purgatory of relapse. This is the stage of disease for which surgical treatment is usually recommended and is often successful. However, not all "advanced" patients require this surgical interference but for some it must be considered immediately if their chances of arrest are not to be squandered in dangerous procrastination. I am inclined, even in the minimal group, when economic pressure is present, in the face of a continuously but slowly advancing lesion, to apply certain surgical measures. Artificial pneumothorax is, of course, included under this head.

To make myself clear, I include under the head of "advanced" patients all save those in the minimal stage. You will recall that patients in the minimal stage never have a cavity nor can the disease extend below the second rib on one side nor below the clavicles if bilateral. Of course a similar extent of disease in any area of the lung places the patient in the minimal group. In the "advanced" patients there are several conditions of paramount importance in regard to treatment. I refer first to the type of disease, proliferative or exudative, second, to the destruction of tissue, i.e., cavity, third, to the age of the patient, and fourth, to his race. The proliferative type may not force us into immediate action but the presence of an

exudative state indicates a more acute process, a more treacherous disease, that can pass at a bound from a temporizing condition into one that spells defeat or, unfortunately less often, almost as rapidly clear up. The presence of a cavity demands nice discrimination from the physician in charge of the patient. There are several important factors in this connection. First, the size of the cavity (the larger, the more serious), second, its location in regard to the pleura and fissures (the nearer, the less likely the efficacy of simple collapse), third, the condition of the wall of the cavity (absence of a wall under certain conditions is more favorable, the thicker the wall, usually the more serious is the condition), and fourth, the associated disease (the more advanced the more dangerous).

The age of the patient cannot be overlooked. Those in the "teen" ages require more careful watching, more active, more expeditious treatment. If, perchance, the patient be a girl, these requirements are emphasized. Recent studies with the roentgen-ray explain why some of these children are never seen to pass through a minimal stage of the disease. The lesion progresses under cover without exciting symptoms until such time as an acute cold or an hemoptysis draws attention to the lungs, when the disease is found to be already in an advanced stage. The only way to treat such patients is to discover them by routine tuberculin testing and roentgenography applied during their high school days. The resilience of youth favors recovery, its exhilaration lessens the chances of recovery. With increasing years relapse is said to be more frequent, recovery less pronounced, advance of the disease slower.

I have spoken of active expeditious treatment and by this I mean some form of collapse therapy. The most widely used is, of course, artificial pneumothorax. An efficient collapse by this treatment occurs in about 40 per cent of all suitable patients. About three-quarters of these achieve a permanent arrest of their disease. So of those selected for the induction of pneumothorax 30 per cent are arrested. The remaining 70 per cent should not be subjected to artificial pneumothorax for too long a time for unquestionably ineffective or contraselective pneumothorax is dangerous and may hasten the patient toward his death. Happily intrapleural pneumolysis has converted many cases of ineffective into effective instances of collapse, terminating in permanent arrest. Some have suggested that the benefits of artificial pneumothorax are bought with the price of some loss of lung function, more than is entailed in the natural cure, and while this may be so, the appalling death rate in those in whom artificial pneumothorax is tried unsuccessfully, fully justifies the procedure. It is questionable whether this form of collapse treatment shortens the time of curing but undoubtedly it does abbreviate the period of inactivity. While the number of patients suitable for artificial pneumothorax is considerable, the remainder, together with the failures, compose a large group. For these other methods of treatment must be sought.

The phrenic operation follows artificial pneumothorax closely in frequency of use. It has undoubtedly been used at times psychologically to offset the disappointment at failure of other methods. The number of these forlorn hopes is larger than some of us imagine. In carefully selected patients the results of cavity closure are encouraging. They are far better among the moderately advanced type than among the far advanced. (In my experience 62 per cent against 12 per cent.) A temporary phrenic operation removes some of the objections offered to the operation. I have been disappointed in the results obtained when I have employed it to bring about closure of a cavity in a lung partially collapsed by artificial pneumothorax. Combined with scalenotomy or followed by scalenotomy better results may be had in some few instances.

May I say a word about postural rest at this time. Many apparently believe that by placing the patient upon the diseased side the affected lung would suffer less. Many years ago we called attention to the fact that increased movement of the diaphragm on the dependent side compensated for decreased movement of the ribs and vice versa and, furthermore, that it was very doubtful if lying on one side decreased in any amount the respiratory function of that lung. This has apparently been recently confirmed (Pier-son and Newell). If, on the other hand, the diaphragm be paralyzed, then postural rest may prove to be more efficacious. Following the phrenic operation I have used in some patients a shot bag on the chest and have raised the foot of the bed 12 inches. Some of the patients have improved. The use of weights on the abdomen, especially when the left lung is affected, and compression of the abdomen by belts, so helpful in some cases of emphysema, should be more beneficial after a phrenic operation.

A successful thoracoplasty is a highly satisfactory operation. It lingers ever in the back of the mind of both patient and physician, and in the front of the mind of most thoracic surgeons. The immediate results have been greatly improved in skillful hands. It has saved many patients from a speedy death. The ultimate results at the end of five and 10 years have been confused by the frequent improvements in technic and failure to state the condition of the patient at the time of rib removal. The operation has come to stay and it behooves all of us to become familiar with its indications. It often frees the sputum of bacilli, decreases the amount of sputum if any persists after operation, and enables a hopeless invalid to resume a normal life. I shall await with great interest to see how these patients weather the respiratory storms so common during the colder months.

There are other surgical procedures, bilateral artificial pneumothorax, oleothorax, apicolysis, plombage, intercostal neurectomy, excision of the lung, all of which have had their uses and advocates.

Before passing on I should like to emphasize the fact that none of the surgical measures which I have recommended excise the diseased area. These procedures act mechanically to put the lung more or less at rest and so to limit the poisoning, to relax the lung, and to place it finally in such a posi-

tion that the simple measures mentioned under the discussion of the treatment of the "minimal" may now become effective for the "advanced" patients

Now since the therapeutic quadriad is apparently necessary in all instances, it is desirable to decide where it can best be put into practice. For those below a certain economic level, the sanatorium or sanatorium-hospital, rarely a general hospital, is best. The more newly constructed institutions are built really for affording rest for patients, and in them every bed is a "hospital" bed, and all the measures advocated for hastening the formation of fibrosis can be used. Many of the economically independent, under a well trained physician, also do remarkably well at home, so well indeed that change of climate, formerly so strongly advocated, is now neglected to the loss of a certain number of patients. All climates might be divided into two groups, sedative and stimulating. Why some are stimulating is difficult to say. As recovery with or without operative measures depends upon the formation of new connective tissue, increased stimulation would seem in some cases advisable. This may be had, as Dr. Trudeau long ago said, in the middle of the ocean, in the midst of the sands of the desert, or on the mountain. Many may not, as I have said, require this, some unquestionably do.

Complications of pulmonary tuberculosis are apparently growing less frequent. A satisfactory method for the diagnosis of secondary intestinal tuberculosis has been followed by numerous recoveries, after the use of heliotherapy or high vitamin diet, whereas formerly, death usually sooner or later supervened. Laryngeal tuberculosis, considered a fatal complication 30 to 40 years ago, now yields to vocal rest, electrocauterization and heliotherapy. Diabetics, after the onset of pulmonary tuberculosis, formerly usually died when put on the diet considered necessary for the tuberculosis, but now with insulin, and the diet required for the diabetes, they frequently recover. The pleural complications, not uncommon in artificial pneumothorax, and at first so dangerous, now yield to the attack by physician and surgeon. The treatment of the complication of pregnancy depends upon how the patient stands pregnancy, whether the predominating type of disease is exudative or proliferative, and how she can be cared for during and following pregnancy. In active disease, prevention of conception is to be preferred to abortion, which should not be attempted after the third month. Artificial pneumothorax may help many patients to bear one or more children safely.

Syphilis should be treated somewhat mildly while pursuing the usual treatment for the pulmonary tuberculosis.

The medicinal treatment has at present few advocates for no substance has been found that can destroy the bacilli and their contained poisons and not injure the host. The destruction indeed of the bacilli in large enough quantities would, on account of the allergic state, bring most patients to the brink of the grave or totter them into it. The only hopeful result from

chemotherapy so far has been the gold salts. In certain instances they have been found helpful. Search for a new tuberculin, which still goes on, is a confession of a present lack of the desired results. BCG, practically a preventive vaccine, is not for use in treatment. Heliotherapy and roentgenotherapy in uncomplicated pulmonary tuberculosis have afforded no convincing proof of their aid. Psychotherapy, used consciously or unconsciously, by all practising physicians, is still as important as it was in the days of Hippocrates. Occupational therapy has helped many to pass the dragging hours of rest.

Finally I would like to emphasize the thought that recovery from pulmonary tuberculosis depends not only upon what we do for the patient but much upon what he brings with him to the physician, in his head as well as in his lungs. We can assist, but do we improve upon the *vis medicatrix naturae* as brought about by rest, food, air and education?

TUBERCULOSIS AMONG STUDENT NURSES A FIVE YEAR STUDY AT BELLEVUE HOSPITAL *

By J BURNS AMBERSON, JR, F A C P, and H McLEOD RIGGINS,
New York, N Y

THIS study was undertaken to collect accurate information about the incidence of tuberculosis among student nurses, to test the efficacy of a system of early diagnosis and case finding, and to measure the results of a rather rigid system of rest treatment in the cases found. Previously, like many others, we had observed a great deal of tuberculosis in nurses but could only infer its duration, rate of progression and relation to hospital service. Such inferences do not answer obviously important questions. A planned study is necessary, and this must be continued for a period of years. Because of the insidious and variable behavior of the disease, a five years' study was considered to be the minimum needed for our purposes. Accordingly it was started in February 1931.

Bellevue Hospital is a municipal institution with a normal bed capacity of 2333, in addition to an outpatient department registering 2171 visits daily. All types of cases, excepting the acute contagious diseases of childhood, are accepted. The Tuberculosis Service has 174 beds. Tuberculous patients who require specialized treatment, such as surgery, are accommodated on wards of the service concerned. Overcrowding is almost constant in Bellevue. The Tuberculosis Service, for instance, often has an excess of 40 to 100 patients, who are accommodated in cots in the center of the wards and, at unusual times, also in the corridors. In the last five years from 3100 to 3600 patients have been admitted to the Tuberculosis Service each year, 15 to 20 per cent of these cases are found not to be tuberculous. According to accepted standards, the nursing personnel is usually inadequate numerically, and at times the duties of the nurses are extremely arduous.

The nursing staff is made up approximately as follows: graduates (male and female) 625, students (female) Bellevue School of Nursing, 200, students (male) Mills School of Nursing, 67, affiliating students (male and female) 121, preliminary students (female) 45, total 1058. This study is limited to female students of the Bellevue School of Nursing. On admission to the school these women average from 18 to 20 years of age. About half come from cities and half from the country and small towns. One class enters in February and one in September of each year, the number of students in a class varying from 25 to 65. The duration of the course is three years. Upon being accepted for training the nurses see

From the Tuberculosis Service of the First Medical Division of Bellevue Hospital and the Department of Practice of Medicine, Columbia University, College of Physicians and Surgeons.

service in practically all hospital departments. The hours of duty, not including classes, are eight daily for six days a week. One month is spent on the tuberculosis service after the beginning of the second year of training. Here, as in all other departments, the nurses wear gowns when ministering to patients, but do not wear face masks. Cleanliness, especially frequent washing of the hands, is urged upon all nurses, but "contagion technic" is not employed.

Selection of Candidates The selection of young women to undertake the arduous course of training is an important task. Up to September 1933, suitable candidates were accepted for the usual probational period, but, since then, a different and more effective plan has been followed. All candidates now spend a preliminary two weeks' "orientation period" before selections are made. During this time the Health Service of the School, under the direction of Miss Mary M. Sullivan, subjects each candidate to a rigid examination including family, social and personal history, a general physical examination, urinalysis, hemoglobin estimation, chest roentgen-ray, Mantoux tuberculin test, and a psychiatric interview. Personality, emotional stability and intelligence are studied. On the bases of the findings during the "orientation period," the women who fail to qualify physically, mentally, emotionally or otherwise are rejected.

Approximately 8 to 10 per cent of the candidates are rejected during these two weeks. The main physical reasons for rejection have been organic heart disease, established hypertension, general asthenia and tuberculosis. Among 591 candidates examined by roentgen-ray during our five years' study, seven were rejected because of the discovery of pulmonary tuberculosis. These were young women in apparently good health. The finding by roentgenogram of small nodules or scars, usually apical and presumably tuberculous, or of old calcified deposits in the pulmonary parenchyma or tracheobronchial lymph nodes was not considered reason for rejection, but parenchymal lesions of greater size were so considered, even though some appeared partly fibrotic.

Preliminary Tuberculin Testing During the first week in the school the students received Mantoux tests starting with 0.1 mg. Old Tuberculin (New York City, Department of Health). Those who failed to react were tested during the second week with a dose of 1 mg. O.T. On this basis 312 or 57.9 per cent of 539 candidates were positive to the tuberculin test on coming to the school during the five years' period. Since September 1933, 62.9 per cent of 305 have been positive. It was found that about one-third of those who failed to react to 0.1 mg., did react to 1 mg. O.T. No doubt still more would have reacted to higher doses but probably not in such proportion. In this connection we may mention that three women with gross shadows of calcified tuberculous lesions in the lungs or tracheobronchial lymph nodes or both failed to react to 1 mg. O.T. No discrimination with regard to the results of the tuberculin testing was exercised in the selection or rejection of candidates.

Follow-Up during Training During the first year of training an additional number (about 20 per cent) of students are eliminated from the school, usually because of scholastic failure, but, with few exceptions, the remainder finish the course successfully. Each nurse has a physical examination annually. Illness, when it occurs, is caused chiefly by acute respiratory infection. In the five years' period there was one death, caused by acute appendicitis and peritonitis. No difference was detected in the general health of the tuberculin-negative and tuberculin-positive nurses.

Subsequent tuberculin testing was performed on those negative to 1 mg O T on admission to the school. In this way the incidence of new infection could be determined approximately, although, as stated, such a negative test is not absolute proof that previous infection had not occurred. Retesting was done every six months until a reaction was noted. In a group of 143 such students followed from six months to three years, and for whom we have accurate information, 37 became positive to tuberculin during their first year of training, 37 during the second year and 10 during the third. Among 70 "negatives" followed for the full three years of the course, all but 10 became positive. Thus it is seen that the majority of presumably uninfected nurses became infected some time during their course. An interesting observation was that most of these newly positive skin reactions were severe ("four plus"). No significant relationship could be discovered between the first positive tuberculin test and the character of the preceding hospital service. The Tuberculosis Service appeared no more related in this respect than other hospital departments. There was no way of ascertaining how many of these students acquired their first infection while moving among the people of New York City outside the hospital.

Tuberculosis Case Finding In addition to the admission roentgenogram, every student nurse had a chest roentgenogram (flat film) at the end of each subsequent six months. Routine hospital technic was employed, and reexamination ordered if the films were unsatisfactory. Comparisons were made with preceding films and, in case of the finding of any definitely or questionably abnormal changes, the student was examined and studied by appropriate means. During the six months' interval, additional examinations were done when symptoms indicated. The only important problems for differential diagnosis were pulmonary lesions in three cases which proved to be bronchopneumonia.

The important features of newly developed tuberculosis discovered during these five years are presented in the accompanying table. In short, there were eight cases including six with pulmonary lesions, one sero-fibrinous pleurisy, and one spondylitis. One case was diagnosed in the first year of training, three in the second and four in the third. None except the nurse with pleurisy had fever at the time of diagnosis, and the only constitutional symptoms were usually slight loss of weight and fatigue in five cases. None was aware of symptoms suggestive of tuberculosis. A few fine râles were heard in a single localized area in three of the pulmonary

TABLE I

TABLE I

Case	Diagnosis	Symptoms			Physical signs	Extent of lesion by x-ray	Mantoux test on entering school	Interval between first positive Mantoux and finding of lesion	Tubercle bacilli in sputum	Treatment	Result T, Still under treatment A, Arrested W, Working

R B	Tracheobronchial lymphadenitis	0	Moderate	0	0	Moderate enlargement in region of old partly calcified lesions	+			Home 3 months	A W

cases, the other three presented no abnormal signs. None had sputum of any significant amount, and tubercle bacilli were not demonstrated in specimens obtained. Thoracentesis yielded clear serous fluid in the case of pleurisy. The diagnosis of tuberculous spondylitis was made in one case by the orthopedic surgeons on the basis of low back pain and tenderness lasting for three months and the roentgen-ray demonstration of narrowing of an intervertebral space.

The diagnosis of the six pulmonary lesions was made chiefly by roentgenogram. In none of these was the diagnosis suggested by the findings six months previously. The lesions discovered were all presumably of a fresh exudative type. The largest extended from the apex to the second rib on the right and the smallest appeared as a density about 0.5 cm. in diameter. (The diagnosis in this case is questionable, but we include it as being presumably tuberculous.) In the other four the lesions averaged about 2 cm. in diameter, appearing as soft cottony localized patches in the roentgenogram. No cavities were demonstrated. The classification in all cases was Minimal A.

Two additional cases are tabulated in which temporary extensions of old lesions occurred. In one the lesion was a tiny nodule in the pulmonary parenchyma which increased to about 0.5 cm. in diameter and then, by the end of a year, receded to its original size. In the other, a rather marked enlargement of the tracheobronchial and mediastinal lymph nodes, with the symptoms of weight loss and fatigue, occurred. This woman had a number of partly calcified lymph node lesions in this region and also in the cervical region on admission to the school. The swelling subsided within a year, and she has been well and working for a year.

Treatment and Results In two cases with small pulmonary lesions no treatment was advised, and healing has taken place under observation, in one, the tiny focus can no longer be identified. In three other pulmonary cases, strict bed rest was given for two to three months followed by partial rest at home, in one case, and in a sanatorium, in two. The lesions are arrested and healing. In one case, in which bed rest was advised but omitted, an extension of the lesion occurred, but this patient is reported improving under treatment. The nurse with serofibrinous pleurisy recovered completely after five months of bed rest and convalescence and has been working for 18 months. In one case tubercle bacilli were demonstrated in the sputum during treatment.

In these cases, therefore, the lesions were arrested and healed or healing in six and improving in the seventh. No form of collapse therapy has been needed. The nurse with tuberculous spondylitis has recently (February 1936) had a spinal fusion operation and the prognosis is favorable. There have been no deaths from tuberculosis.

Relationship to Tuberculin Sensitiveness Among these freshly developed cases, the Mantoux test as the nurses entered the school was positive in two and negative in six, but in one of the six a calcified tuberculous

focus about 1 cm in diameter was demonstrated by roentgen-ray. If we supplement this small series of cases with observations we have made among other nurses at Bellevue, we do not find any definite trend. In other words, the occurrence and behavior of tuberculosis in all nurses coming under our observation thus far have not varied significantly in relation to the results of preceding tuberculin tests. It should be noted that no freshly developed lesions in the tracheobronchial or mediastinal lymph nodes were demonstrated in those who became tuberculin-sensitive under observation.

Observation after Graduation This study does not include any methodical case finding among the nurses who have graduated from the school. However, the 135 who have graduated in classes included in the study are almost all employed in the hospital and we have their general health records from six months to two years after graduation. During this time one new case of "minimal" pulmonary tuberculosis has been found among the 135 graduates. Two others have had one attack each of erythema nodosum, both have recovered and neither has shown any evidence of tuberculosis. Since the etiology of erythema nodosum is disputed we do not include these among our definite cases. We have no evidence to lead us to believe that the occurrence of erythema nodosum favors the later development of tuberculosis.

Tuberculosis Case Rate Because of the relatively small size of the group included in our study the morbidity rate from tuberculosis during these five years cannot be expected necessarily to represent a definite trend. Another five years' observation will establish this more accurately. Excluding two cases in which the observed changes certainly indicated temporary inflammatory reactions about previously established lesions, the eight cases in which we detected newly developed lesions represent 1.6 per cent of 492 young women who entered the school as students. However, because of variations in the length of observation, these figures have little meaning. The experience is better expressed as follows:

A total of eight nurses developed new tuberculous lesions during the course of training, representing a case rate of 1.09 per 100 nurses per year.

Seven of these were lesions of the lungs or pleura, or 0.95 per 100 per year.

Five of those with pulmonary or pleural lesions required treatment, or 0.68 per 100 per year.

Enumeration of cases, alone, is misleading, especially when the lesions are small, because it affords a very inadequate idea of the actual seriousness of tuberculosis in any group. In six of these eight cases, the lesions have healed or are healing well with or without treatment. According to sanatorium experience, the expectancy of health and life in these six should be very close to normal. In the remaining two (one pulmonary case and one spondylitis) still under treatment the disease may be said to constitute a serious threat, although the prognosis at present seems to be favorable for eventual recovery. Including the three cases under treatment and basing a

tabulation on the entire group of student nurses included in the study, it is indicated that the loss of time on account of tuberculosis during the five years was 27 days per nurse per year

Other Bellevue Nurses It has been shown that tuberculosis in Bellevue student nurses was discovered mainly by regular roentgenographic examination of the chest before the pulmonary lesions had progressed beyond a "minimal" stage, before excavation had occurred, and before definite symptoms had developed. The great value of such a case finding procedure is proved by contrasting our experience with other groups made up of graduate and affiliating student nurses at Bellevue. These groups did not come within our study, and consequently reported for examination as a rule only when they had definite symptoms. Graduates, of course, were more aware than affiliate students of the insidious character of symptoms of tuberculosis. In six years we have discovered tuberculosis in 26 nurses from these two groups. Five had pleurisy with effusion alone. Among graduates we discovered seven minimal lesions, six moderately advanced, and two far advanced, among affiliates, none minimal, five moderately advanced and one far advanced. In both groups, therefore, the lesions were in a moderately or far advanced stage in 67 per cent of the cases when the nurses first developed symptoms sufficiently impressive to indicate to them the need of an examination. This coincides with the experience in the tuberculosis clinics in New York City and in practice generally.

Costs The cost of finished roentgen-ray films for the Bellevue school enrollment was about \$500 a year. Other costs were absorbed in the general functioning of hospital departments and the Health Service of the school. The results, if measured in terms of early diagnosis and prevention of chronic disabling illness, fully justify the expenditure. Economically, it must be considered that early diagnosis saves many thousands of dollars by shortening the period of treatment and restoring nurses to almost full working capacity. One Bellevue graduate, employed in the operating room, was found to have advanced bilateral pulmonary tuberculosis when symptoms first led her to report for examination. She received treatment for five years at a cost of at least five thousand dollars, and at the end of five years she died.

COMMENT

The experience indicates that student nurses entering Bellevue Hospital with negative tuberculin tests became tuberculin sensitive at a rate somewhat in excess of that which would be anticipated in the general community. This observation alone, however, does not suffice to measure the hazard of clinical tuberculosis in relation to that which prevails for the community at large. It must be considered as Dublin¹ finds, that the tuberculosis death rate among white females in the general population ascends to its peak in the 20 to 24 age group. Likewise, there is customarily a striking accretion of new pulmonary lesions. Fellows² reports an incidence of new

lesions of clinical importance among 4000 female employees, aged 18 to 22, in the home office of the Metropolitan Life Insurance Company in New York City, amounting to 0.25 per hundred per year. This rate, established by observation of the group from January 1932, until June 1935, applies to cases in which treatment was usually indicated. In our group the case rate was approximately 0.68 per hundred nurses per year of new pulmonary or pleural lesions requiring treatment, but the incidence of all new lesions was 1.09. The comparison of rates alone, however, is not valid for the following reasons: (1) Our group is small and later observation may reveal a different trend of morbidity, (2) Our cases were found by roentgenogram which is known to reveal more small lesions than the fluoroscopic method which Fellows and his coworkers employ, (3) Tiny pulmonary lesions may appear and recede to insignificant dimensions within a year, and a semi-annual roentgenogram will occasionally reveal one of these which would be missed by an annual fluoroscopy, (4) Fellows' statistics do not include tuberculosis outside the lungs and pleura, (5) Other factors, such as racial stock and time for adaptation to city life, are not considered.

During 1935 the days lost from work on account of tuberculosis by Metropolitan Life Insurance Company home office employees, aged 17 to 35, was 2.6 per female per year. The similarity of our average of 2.7 per nurse per year during the five years' period is interesting, therefore, even though we draw no conclusion from the comparison.

Age distribution of new cases is not known for New York City, but with a death rate of 85, it may be assumed that at least 170 new cases of tuberculosis per 100,000 females in this age group are reported to the Board of Health annually, that these are almost all symptomatic cases, that they are cases of advanced disease in at least 70 per cent of the instances, and that they represent only a fraction of newly developed lesions. Therefore, while we have no basis of comparison for all newly developed lesions, it is clear that, with the system of case finding and control described, the hazard of serious and advanced tuberculosis for Bellevue student nurses has not exceeded that for young women pursuing other occupations in the City.

During the past six years, 50 young physicians have served as resident physicians or interns, some for six months and most for at least one year, on the Tuberculosis Service. Two, both women, are known to have developed clinical pulmonary tuberculosis. In one case this was an extension from a fibrotic lesion which was present when the physician came to the Service, in the other, fairly large apparently calcified lesions in the lung and tracheobronchial lymph nodes were identified previously.

In considering this problem as it concerns the nursing and medical profession generally, further methodical studies are needed on which to base fair judgment. It is to be anticipated that the incidence of tuberculosis will continue among nurses who have graduated but, thus far, we have not proved it to exceed the expected community rate. In a recent analysis of death rates by occupation, Whitney³ finds that the standardized mortality

rate from tuberculosis of the respiratory system among male physicians and surgeons in 10 selected states was 23.7 per 100,000 in 1930. This compares with a mortality of 175.3 among all gainfully occupied males, 15 to 64 years of age. Next to lawyers, judges and justices, with a rate of 18.3, physicians and surgeons enjoyed the lowest rate among all gainfully occupied males in these states.

Our study demonstrates anew the remarkable tolerance of adult human beings for infection with the tubercle bacillus, even in an environment where the opportunities for infection are great. It is again apparent that infection is only one factor in the combination which makes for clinical tuberculosis, though it is obviously the necessary one. It is, of course, highly desirable to avoid infection if possible, but at present this is not wholly possible either in Bellevue Hospital or elsewhere in New York. Other safeguards against the development of serious, chronic, disabling and fatal tuberculosis should be set up not only in nursing schools but also among other groups, particularly among young people generally. Methodical case finding in such groups will almost always detect the presence of tuberculosis in its earliest clinical phase—the only phase in which the disease can be considered curable in 80 to 90 per cent of the cases.

CONCLUSION

During the past five years tuberculosis among nurses in the Bellevue Hospital School of Nursing has been controlled so that its seriousness as a disabling and fatal disease does not appear to exceed that expected among young women in other occupations in New York City.

We wish to express our thanks to Miss Mary M. Sullivan, Director of the Health Service of the Bellevue Hospital School of Nursing, for her assistance and cooperation. Acknowledgments are also made for the cooperation of Dr. Clarence E. de la Chapelle, physician to the Health Service, and for the interest and suggestions of Dr. Haynes Harold Fellows, Assistant Medical Director of the Metropolitan Life Insurance Company.

THE DIAGNOSIS OF SILICOSIS, WITH SPECIAL REFERENCE TO ROENTGENOLOGICAL MANIFESTATIONS *

By LEROY U GARDNER, M D , *Saranac Lake, N Y*

BECAUSE conditions caused by the inhalation of dust are so frequently involved in litigation it is necessary that they be defined with the greatest clarity. Our terminology developed forty to fifty years ago, before the pathology of such conditions had been worked out. Pneumoconiosis was the term coined to designate disease of the lungs due to inhaled dust, regardless of its nature. Anthracosis, siderosis, chalicosis, silicosis were specific forms of pneumoconiosis due to inhaled coal, iron, stone dust and silica respectively. All were considered of equal significance as it was believed that any dust was merely a foreign body which, when inhaled in excess, would produce scar tissue. Then came the discovery that silica was different, that it acted like a poison and caused a specific and progressive fibrosis. If the inhalation of iron or coal dust caused damage it was because they were mixed with appreciable quantities of silica. Other dusts, with the exception of the silicate, asbestos, were apparently quite harmless. The search for still other dangerous dusts is being continued but thus far none has been discovered.

The original terminology is firmly fixed in the literature and it is still valuable if it is used intelligently, but not all medical men are yet familiar with these more recent discoveries, and non-medical persons are apt to be confused by the implications of the terms. It would seem preferable to use the term, silicosis, for progressive disease of the lungs produced by inhaled silica dust. If, in addition, the lungs happen to contain significant quantities of coal or iron the compound terms, anthraco-silicosis or sidero-silicosis, are descriptive. Inhalation of relatively pure coal or iron produces no change that should be interpreted as a disease process. They cause pigmentation but this is disease only in the same sense as the callouses on the palms of the hands, or the pigmentation of the skin from prolonged exposure to the sun. Such changes are in a strict sense pathological but they do not interfere with function and are therefore not ordinarily classified as diseases.

For the same reason the writer would prefer to abandon the use of the term, pneumoconiosis. Its implications are too broad, it connotes a *disease* process when actually its user may have in mind a benign pigmentation of the lungs with or without slight proliferative changes. It is sometimes a convenience to the pathologist in making an anatomical diagnosis of a condition due to some dust whose action is not yet defined. It is also a convenience to the roentgenologist, but he cannot see the dust in his shadows as the pathologist can in his sections. Far too frequently the film is labeled "pneumoconiosis" because of a history of dust exposure. To the

* Read at the Detroit meeting of the American College of Physicians, March 5, 1936

non-medical mind the term means disease with as serious consequences as silicosis. If it is to be retained, pneumoconiosis should be defined as a *condition* of the lungs resulting from the inhalation of dust that may or may not be of clinical significance.

This paper will point out the specific nature of the reaction to silica, it will attempt to show that no other dust, with the exception of asbestos, is known to produce significant amounts of fibrous tissue in the lungs. It will also indicate the important relationships between silicosis and tuberculous infection.

Space will not permit a review of the numerous observations leading to the conclusion that silica is unique among inorganic materials in exciting a progressive fibrosis of the tissues. It must suffice to state that the injection of a suspension of minute silica particles produces a localized acute inflammatory response associated with phagocytosis by mononuclear cells. This is followed by necrosis and subsequent repair characterized by the formation of a nodule of swollen, hyalinized connective tissue fibers. The finer the particles the more rapid the response of the tissues. Within limits the reaction is a progressive one but, being nodular in type, progression is manifested by a slow increase in size of the original area of involvement. Injection of the same amount of the same sized particles of non-siliceous substances like carborundum, emery, diamond, coal, iron oxide, etc., causes a transitory inflammation with phagocytosis but the lesion is not nodular, it is followed by no necrosis, only a few connective tissue cells are formed and none of them form hyaline fibers.

Many observers are of the opinion that the silica particles dissolve and thus poison the tissue, but this contention cannot be proved by chemical methods. Indirect evidence would seem to substantiate this view but silica, or quartz, is only very slightly soluble at the hydrogen-ion concentration and temperature of the body. Reaction to injected silica occurs within an hour or two, which is difficult to reconcile with the solubility hypothesis. The writer believes that silica is a tissue poison but that some property other than solubility is responsible for its irritating effects.

Gunea pigs and other animals made to inhale pure silica dust for eight hours a day, over a period of a year or more, develop nodular fibrosis of the lungs that is quite comparable with the lesions found in human beings with silicosis. Their disease begins with phagocytosis of the dust particles in the air spaces, migration of these dust-containing cells into the lymphatic system, and concentration of the foreign bodies in the areolar tissues along the vessels and at focal points in the lymphoid tissues. Proliferation of the local connective tissues follows, producing perilymphatic sheaths of fibrosis and tubercle-like nodules of fibrosis in the lymphoid tissues. Because of their position the expanding nodules tend to compress the adjacent lymphatic vessels. The free flow of lymph from the lung is impeded and subsequently inhaled dust is more apt to remain in the air spaces.

With the drainage system of the organ impaired the phagocytes tend to carry dust particles into the walls of the air spaces. Proliferation of the connective tissues in this location causes both nodular and diffuse fibrosis. The latter is more prone to occur when the dust concentrations are high and the foreign bodies accumulate much faster than they can be removed by physiological mechanisms. The nodular foci of reaction exhibit the same evolution as that described for injected silica. If the dust accumulates slowly, necrosis is slight and may involve only a few cells at a time, if it accumulates rapidly necrosis may dominate the picture. In rabbits, and sometimes in guinea pigs and human beings, necrosis is ultimately replaced by calcification.

Inhaled mineral *particles* other than silica are phagocytosed by the same kind of cells and many of them removed to the lymphatic system. There is a decided tendency for some of the phagocytes to become overloaded so that their motility is impaired and they remain with their ingested material inside the air spaces. Since much of the dust makes its way to the alveoli beneath the pleura, the surface of the lung is pigmented if a colored dust is involved. These mineral particles do not actively stimulate connective tissue, and no appreciable proliferation occurs. After one or two years of exposure to heavy concentrations of such dusts one finds accumulations in the superficial air spaces, in and along the lymphatic trunks that course through the walls of the vessels, in the lymph nodules inside the lung, and in the lymph nodes at their roots. Such deposits stimulate only the very slightest proliferation of connective tissue. From its location such reaction can hardly affect pulmonary function.

Animals breathing the *fibers* of the silicate, asbestos, show a third type of reaction. A considerable number of these fibers are able to pass the barriers of the upper respiratory tract and to slip along over the surface of the ciliated epithelium lining the bronchi. When they reach the sacculated walls of the respiratory bronchioles they are caught in the lateral alveoli and practically none are carried onward into the terminal air spaces. This type of foreign body seems to present a new and difficult problem to the defense mechanisms. Phagocytes and giant cells attempt to ingest the fibers but they are apparently unable to transport them. Most of the cells remain in and along the walls of the terminal bronchioles where they first lodged, only very rarely can fibers be found in the lymphatic system. In the presence of complicating infection a few may be transported to the lymph nodes.

All of the reactions to fibrous asbestos thus far observed have been confined to the region of the terminal bronchioles. The reactive process starts as a collar of cellular fibrosis about these structures and during a three year period of exposure the only appreciable extension has occurred peripherally along the alveolar ducts given off from the ends of the bronchioles. The ultimate alveolar sacs and alveoli are uninvolved and no reaction is detectable in the lymphatic system. The resultant picture is that of small, isolated patches of fibrosis lying in an otherwise normal lung. The characteristic

asbestosis bodies that are found in human beings are reproduced in guinea pigs. Rabbits have not developed them because their upper respiratory mechanisms are apparently adequate to prevent the penetration of fibers. Their lungs showed no fibrosis.

Only these three general types of reaction have thus far been discovered. The silicosis picture may be modified when the dust causing it contains varying quantities of non-siliceous substances like coal and iron. Under such circumstances the adulterant dust particles are not so uniformly segregated in the superficial air spaces and in the vicinity of the lymphatic system. Many of them are carried to the periphery of the silicotic nodules where they, and some of the silica, are responsible for the formation of an irregularly radiating zone of thin fibrous tissue. This disturbs the usual compact nodular arrangement of the typical silicotic lesion. The matter of protection against silica by adulterant dusts is still under investigation and cannot be discussed here. It is possible that other types of reaction, as unusual as that to asbestos, may sometime be discovered, but thus far only the three that have been described are recognized.

The effects of inhaled silica, asbestos and non-siliceous dusts upon tuberculosis have been tested in experimental animals by administering a primary inhalation infection with attenuated tubercle bacilli. In normal guinea pigs such infection causes a self-limited lesion comparable to the primary complex in man. A year or two after infection most of the tubercles have healed and largely disappeared. In silicotic animals such infection, administered at the time when the dust exposure begins, produces a chronic progressive tuberculosis that usually kills after a period of 18 months to two years. If the infection is introduced when the silicosis is fully developed the animal dies in from one to three months. Inhalation of silica instituted after the infection, when most of the tubercles are healing or healed, causes reactivation and spread from any foci that still harbor living bacilli.

In the case of asbestosis, infection, after the disease is established, runs practically the same course as that in normal control animals. Infection simultaneous with the onset of dust inhalation shows no unusual effects for six to eight months. Then it begins to spread locally in about one-half of the animals, in the others there has been no appreciable effect. Where spread occurred the process was fatal in a few instances, but in animals that survived the acute stages healing and fibrosis were the ultimate outcome. With inert dusts the infection runs a normal course if it is administered when the dust exposure is started. If it is given after some months of dusting it subsequently heals and either resolves or leaves more scar tissues than usual.

These experimental observations have been valuable in interpreting the terminal stages of various human pneumoconioses seen at the autopsy table. They, with the occasional case dying of accidental causes after short exposure, and a large amount of roentgenographic material, have made it

possible to build up pictures of the evolution of these conditions in man. In considering this phase of the subject the roentgenogram will be taken as the point of departure. The various shadows seen in different forms of pneumoconiosis will be explained in the light of known pathological reactions.

In silicosis, the first pathognomonic shadow is that of the fine nodule in the parenchyma of the lung field. Such shadows are discrete, sharply circumscribed, never more than 6 mm., and usually not more than 2 or 3 mm. in diameter, and uniformly distributed throughout both lungs. The inhalation of silica produces other changes before parenchymatous nodulation develops but such changes are not specific and they are readily confused with the reaction to non-siliceous dusts. They consist of an accentuation of the linear markings of the lung due to reaction in and about the lymph trunks traversing the walls of the blood vessels. Perfect stereoroentgenograms may reveal the minute silicotic nodules in the intrapulmonary lymphoid tissues that are situated at the bifurcation of blood vessels. There may also be enlargement of the mediastinal shadow due to the reaction to the silica brought to the tracheobronchial lymph nodes. But such changes are not specific, they may be caused by pulmonary infection. The linear exaggeration is equally well produced by the inhalation of non-siliceous dusts. Therefore, even in the presence of a history of several years' exposure to silica dust, one is not justified in diagnosing silicosis unless he sees the characteristic nodular shadows in the lung fields.

In addition to generalized discrete nodulation, simple silicosis may exhibit massive conglomerations in localized areas of the lungs. The shadows of conglomerate lesions are frequently seen in films of persons exposed to mixtures of silica and other substances like coal. It seems probable that such reaction develops in areas where the lung tissues have been injured by previous infections that have subsequently healed. As the result of the injury more dust, and consequently more fibrosis, occurs in the localized area. Individuals with such pictures have no symptoms of active infection, although they are usually quite dyspneic. Serial reexamination over a period of years reveals no change in the character of the pulmonary shadow.

When tuberculosis is superimposed upon silicosis it may manifest itself as simple superimposition or as a new type of disease known as silico-tuberculosis. The *primary complex* of tuberculosis can be detected on a background of generalized nodulation. The silica rarely has any effect upon these foci as they are generally sterile by the time persons begin to work in dust. Very rarely they have been reactivated and spread in a manner similar to that described in the guinea pig. The scars of healed *apical tuberculosis* are recognizable in the silicotic lung. After prolonged exposures to dust such lesions have been seen to break down and give rise to very chronic silico-tuberculosis, a conglomerate type of disease, that spreads slowly from the vicinity of the original focus harboring bacilli. This lesion is productive rather than exudative in character, cavity formation, if it occurs, is

a late manifestation *Aspiration and bronchogenic* spreads to remote portions of the lungs are limited. The sputum is usually negative until late in the disease. Clinical symptoms of intoxication are slight. Silico-tuberculosis is much more commonly found in the base of the lung than simple tuberculosis. Whether the basal lesion of the silicotic is a manifestation of exogenous reinfection or whether it originates from reactivated latent foci has not been determined.

The focus of silico-tuberculosis may be difficult to differentiate from the conglomerate focus of simple silicosis, but the former being due to an active infection is constantly, though slowly, changing and its bearer will be apt to manifest some clinical evidence of it. Repeated examinations by all available methods are essential for a diagnosis.

Miliary tuberculosis occurs as a terminal event but it is particularly difficult to detect in the roentgenogram showing generalized discrete nodulation.

Pneumonia may complicate silicosis but whether it is any more frequent than in normal populations is debatable. Probably the same factors that favor its development in others are operative in the silicotic. If it occurs, failure of resolution and resultant organization are probably more frequent in the presence of complicating silicosis.

The roentgenographic picture of non-injurious dust reactions has already been mentioned. It is essentially characterized by an increased density and prominence of the linear shadows of the blood vessels in the lungs. This is due to the thickening of their walls from reaction around the lymphatic vessels that they include. There may also be a fine reticulation in the periphery of the lung from reaction about the lymphatics that course through the pleura and interlobular septa. Whether accumulations of dust in the subpleural alveoli intercept enough roentgen-rays to cast a shadow is still debated. It seems doubtful. Healing of an infectious process in a lung containing large quantities of any kind of dust is apt to be less perfect than that in a normal organ. If the infection has been widespread it may leave confusing residua that may be wrongly ascribed to the action of the dust. Such faulty interpretation can be avoided by the study of a sufficient number of persons, exposed to the particular dust in question, to establish a proper standard of comparison.

The pathology of asbestosis in the human subject needs further investigation. Present knowledge is based upon the terminal stages seen in a relatively small number of postmortem examinations. In many of these cases death has occurred from pulmonary infection, which further complicates the picture. Roentgenograms of living tuberculous subjects generally seem to depict a less severe type of reaction than that found in the "uncomplicated" case at the autopsy table.

The roentgenogram of moderately advanced asbestosis is usually characterized by a diffuse "ground glass haziness" throughout the lower parts of the lung fields. As the disease evolves, the haze spreads and the upper portions are involved. In advanced stages there is a generalized, fine

speckling throughout the lungs. The shadows simulate very fine nodulation but they are smaller and less clearly defined. In addition there is sometimes evidence of chronic pleurisy and there may be heavy linear shadows radiating from the borders of the heart. The latter are responsible for a condition labeled "the porcupine heart."

It is not yet clear whether asbestosis in the human being develops in the same fashion as the experimental lesions in guinea pigs. The detection of occasional masses of fibrosis about terminal bronchioles suggests that it does, but in all of the seven human cases that the writer has thus far had opportunity to study there have also been other and more complex fibrous reactions. If one may speculate on the probable pathological reaction responsible for the shadows seen in the roentgenogram, one would infer that the diffuse haziness of the lower lung in moderately advanced disease is caused by the superimposed shadows of innumerable collars of reaction about small terminal bronchioles. It is frequently asked why the first manifestations should appear in only one part of the organ. Probably all portions receive an equal share of inhaled particles if one can trust the appearances seen in human and animal autopsies. The writer's confrere, Dr H. L. Sampson, has suggested that in the thicker layer of tissue penetrated by the roentgen-ray at the base of the lung there would be so many more of these fine lesions that they would cast a shadow, whereas in the thinner upper lung there would not be enough of them to intercept sufficient rays to cast a visible shadow. As these peribronchiolar foci of reaction grew larger and more fibrous with advancing disease they would become more dense and cast definite shadows. The shape of such shadows would vary with the angle of incidence of the rays upon the different lesions, some would appear as rounded spots and others would be elongated. This would explain the fine irregular stippling seen in more advanced cases. The pleural thickenings and linear shadows radiating from the borders of the heart find no explanation in the disease thus far produced in guinea pigs. It is of course possible that longer exposure might cause further changes in the lungs but thus far there has been no hint of such change, unless the asbestosis was complicated by infection. The small amount of human material that the writer has studied also suggested that healed infection was responsible for much of the fibrosis observed. However, this conclusion is provisional and may be modified when further observations become possible.

The incidence of tuberculosis complicating asbestosis is variable in different parts of the world. In Great Britain, Merewether¹ reports 35.7 per cent, in cases that have died, against 59.4 per cent for silicosis. Gloyne² found 17.5 per cent. In this country, Lanza, McConnell and Fehnel³ found only one active case of tuberculosis in 67 cases of silicosis examined by roentgen-ray (1.5 per cent), seven cases showed healed tuberculous lesions. In guinea pigs, it will be recalled, asbestos dust seemed to create some tendency for tuberculous infection to spread but the effect was usually

transitory and was not manifested in all animals Healing was attended by excessive fibrosis

SUMMARY

Regardless of the history of exposure to dust, a diagnosis of silicosis should not be made until generalized discrete nodular shadows are visible in the lung fields. Large localized shadows suggest complicating infection but there is a conglomerate type of simple silicosis that occurs in the absence of active infection. It may result from pulmonary damage by previous infection that has healed. It can only be differentiated from active infection by careful clinical study and by repeated roentgenograms to exclude change in the character and size of the lesion. The silicotic lung may exhibit the usual manifestations of tuberculosis, superimposed upon a background of generalized nodulation, more common are the massive foci of consolidation due to silico-tuberculosis. These may be situated in the upper parts of the lung where they result from reactivated apical foci of tuberculosis but frequently they occur in the mid or lower lung. They consist of a very chronic combination of tuberculosis and silicosis progressing simultaneously in the same area. They give rise to much less pronounced symptoms of intoxication than tuberculosis alone. More acute forms of tuberculosis, aspiration disease, and miliary tuberculosis occur but they are not very common.

Non-siliceous dusts are generally responsible for an exaggeration of the linear markings of the lung. As far as known the slight perilymphatic reactions responsible for them do not interfere with pulmonary function and they do not alter the native susceptibility to tuberculosis.

Asbestosis is not so well understood. The roentgenogram shows a diffuse haziness of the lower lung fields and later a very fine uniform stippling. Whether chronic pleurisy, increased linear markings and conglomerate shadows are due to the dust, to secondary changes incident to collapse of lobules, or to complicating infection, has not been definitely settled. The appearance of a tuberculous lesion in the asbestosis lung is apparently not modified. There may be some tendency toward chronicity.

SILICOSIS FROM THE PUBLIC HEALTH AND ECONOMIC VIEWPOINT¹

By A J LANZA, M D, *New York, N Y*

SILICOSIS is essentially a chronic progressive disease, characterized by an extraordinary tendency to tubercle infection. It occurs only as an occupational disease, and the industrial processes associated with exposure to silica dust vary widely and are distributed over many dissimilar industries.

The time factor in silicosis is a lengthy one. This, together with its progressive nature, tends to complicate and confuse our efforts to deal with the silicotic patient either when he is an applicant for compensation benefits or the subject of litigative or legislative procedure. Obviously, the rate of development in a disease caused by the inhalation of dust is determined by several factors. There are the amount of free silica in the dust, the amount of dust in the atmosphere, and the extent of exposure of the individual. We estimate the severity of the hazard in any given case by weighing these three factors.

Where the amount of free silica in the dust is very high—80, 90, or 95 per cent—and the quantity of dust excessively large and the exposure constant, then the physician sees the severe or, as Gardner has termed it, the classical form of silicosis, which develops in from five to ten years, progresses steadily, and almost inevitably is complicated with a tubercle infection which runs its course fairly rapidly. This is the type of silicosis described in the early literature and found especially in mines where the rock was highly siliceous and drilling was done dry and no adequate preventive measures were enforced—a type of silicosis which is disappearing and will soon be relatively infrequent in this country.

Spread throughout industry are many dust hazards in which the combined weight of the three factors is less than under the conditions just described—the amount of silica may be relatively low—15 to 50 per cent—the quantity of the dust may not be so excessive, the exposure may be less constant, and more or less effective efforts at dust control may be attempted. In this situation, the clinical picture is one of very slow development, made evident only in the higher age groups, with little disability in the absence of infection, and a less pronounced incidence of tuberculosis.

In between the very severe and the mild types of silicosis are many gradations, resulting from the emphasis or lack of emphasis of one or more of the factors mentioned. I desire to stress the importance of establishing and evaluating these causative factors in every case of silicosis. The failure to do so has been largely responsible for much of the misapprehension and

* Presented at the Detroit meeting of the American College of Physicians, March 5, 1936

confusion that have characterized attempts to deal with the silicosis problem during the last few years

The extent of the exposure to the silicosis hazard is greater than might be supposed. The following figures are quoted from a study of the subject by Vane and the author¹. We estimated that there are about 115,000 miners in metal mines and coal mines exposed to silica dust—by no means all of the men employed in these industries. Workers in smelters, foundries, glass works, together with those employed as grinders, sandblasters, and vitreous enamellers, would account for about 325,000. Including also various other occupations with a known silica hazard, we arrived at a total of not less than 500,000 workers exposed to silicosis in this country and this, in our opinion, is a very conservative estimate.

At any rate, the burden of silicosis, both in sickness and in cost, is staggering. From the viewpoint of public health and preventive medicine, it is a shining target to shoot at. The situation is not new. What is new is the attention that has been focused on pulmonary dust diseases in the last five years, with the consequent tendency to include silicosis among the compensable diseases. The difficulties of applying the principles of compensation to an insidious and chronic disease are apparent. It is not my purpose to discuss them here. But it would seem that if these vexatious difficulties are to be overcome, a competent medical board should be an integral part of the compensation mechanism. It is, perhaps, too much to hope that there should be uniformity in the practice of the different States with respect to a standardized diagnostic procedure, but unless competent medical assistance can be made available in carrying out the provisions of occupational disease compensation laws, they cannot be administered with justice nor with a proper regard for the public interest.

The control and prevention of silicosis is, in the main, a medical problem. Upon the physician falls the responsibility of accurate and precise diagnosis—first, to determine whether the applicant for work, where a dust hazard may be present, is free from pulmonary or other disease which should bar him from such employment, and second, to discover as early as possible the indications of harmful effects among those employed. As a judge, deciding who should or who should not work in any given occupation, where an occupational disease hazard is involved, the physician renders a service to the public health as important and exacting as any professional function he may be called on to fulfill. I dwell upon this because it seems inevitable that the physician is going to be interjected into the industrial picture to an increasing extent. While it may be desirable to set up standards of employment in this matter of occupational disease hazards, such standards must be very general. There is no substitute for the personal judgment and experience of the physician, coupled with a first hand knowledge of working conditions. Each individual is a case in himself, and social and economic conditions may demand consideration as well as his physical condition.

The mitigation of the dust hazards falls within the realm of the engineer but the proof of the efficiency of engineering control methods must be determined by the presence or absence of specific pathological changes in the individuals involved. In any situation where silica dust may be a hazard, the information we seek is the percentage of silica in the dust and the number of million particles per cubic foot of air in the working place. The method of sampling and analyzing dust air in working places has been standardized by the United States Public Health Service and the United States Bureau of Mines. Their technic has been generally adopted by competent investigators. The air sample is taken with the Greenberg-Smith impinger, large samples averaging about 100 cubic feet being secured on a level with the workman's face and at a rate approximating that of normal breathing. The sample is analyzed for free silica, and from microscopic preparations the particles are counted and the size-frequency determined. Under most industrial conditions, about 90 per cent of the particles are under ten microns in size. While dust determinations do not come within the physician's duties, he should be able to evaluate the information obtained, otherwise he cannot determine who should be employed and who should be rejected, nor who should be transferred to another job, and who retained.

Workmen exposed to a silica hazard should be examined periodically. An annual examination may be sufficient but the judgment of the physician must be the deciding factor and he should have the right to reexamine those under his care as often as he deems advisable. When a workman is found to have silicosis, he should be protected from further dust exposure—if necessary transferred to another job. When a silicotic becomes tuberculous, he should be placed upon complete disability, both in his own interest and that of his fellow workmen.

From the point of view of diagnosis the value of the roentgenogram has been stressed. While it is true that a roentgen-ray film of the chest is essential, it should be recognized that there is a tendency to disregard other necessary and important diagnostic information. It is a common occurrence for films to be sent to our office for confirmation of a diagnosis with no case history or clinical data whatsoever. A complete occupational history as well as a clinical history, and a thorough physical examination are necessary if the film is to be correctly interpreted. It is also vitally important that the physician who attempts the diagnosis of silicosis be familiar with the general appearance of chest films of working men so that he may be conversant with the various appearances that are compatible with what has been aptly termed "the healthy chest."

The attention that has been centered upon the various pneumoconioses in the last few years has revealed the tendency to disregard occupation as one of the important factors in the clinical history of patients who come from the wage earning class. It is unusual to find an accurate occupational history in either private or institutional records, which is one of the reasons why occupational diseases are not diagnosed more frequently. Espe-

cially where the disease is essentially chronic, as in silicosis, a careful building up of the work history of the patient, from the time he left school to earn his living, may be the only key that will unlock a diagnostic puzzle

I would also like to point out that the clinical picture of silicosis among negroes is not the same as among whites. The negro is not as resistant to silica dust, he becomes tuberculous more readily and he succumbs more quickly. Where the silica dust exposure has been very severe, the clinical picture among negroes may approach the acute in type whereas among white men, working on the same job, it will be characteristically chronic.

An important phase of the silicosis problem is the incidence of tuberculous infection among the families of silicotics. In the early literature, especially that relating to the mining industry, the widow who had buried several husbands with miner's consumption was much in evidence. From this arose the general belief that there was not much spread of infection from silicotics with tuberculosis to their families. Undoubtedly, the situation varies locally and is influenced by race, general hygienic conditions and the severity of the hazard.

As a rule, the silicotic does not live long after his tuberculosis becomes open. Cummings of Saranac, in a study made in the Picher, Oklahoma District (unpublished) found evidence of tubercle infection in over 50 per cent of the children under 16 living in contact with silicotic patients having a positive sputum, but the infection was entirely of the primary type and there was no progressive adult tuberculosis. The whole subject of infection needs further study. We do not know what is the nature of the affinity between silica and the tubercle bacillus.

It is, unfortunately, a characteristic of silicosis that it tends to progress even when there is no longer an exposure to silica dust. The workman with a considerable degree of silicosis has an unfavorable prognosis even though he is removed from further dust exposure. He will probably succumb to tuberculosis. Where the damage to the lungs is slight, or moderate, he may go on for many years with little or no disability, but the overall mortality from respiratory diseases, particularly tuberculosis, among the silica dusty trades bears ample witness to the harmfulness that lies inherent in exposure to silica.

One of the difficulties that is constantly present in dealing with individual cases of silicosis is the estimation of the degree of disability. We would expect this in any chronic disease. The roentgen-ray film is not a satisfactory criterion. There may be evidence of a considerable amount of pathologic change in the film and yet the patient may look fairly well and be conscious of little impairment of his working ability. Chest expansion gives us no clue and little can be estimated from the patient's statements concerning dyspnea except in the advanced cases. Furthermore, it is not always possible to be certain of the presence or absence of infection—either from the symptoms or the roentgen-ray film. As a result, there has been a definite tendency to award compensation or other benefits on the basis of

a diagnosis rather than on actual disability—a most unsatisfactory condition of affairs. Some promising research has been started for the purpose of estimating impairment of pulmonary function without as yet producing results that can be converted into procedures for the clinician.

To sum up, silicosis is a widespread disease and is responsible for much tuberculosis among wage-earners. Its detection and control depend upon the accuracy and timeliness of diagnosis. As with other phases of the public health, successful achievement rests with the physician.

DIABETES TODAY AND TOMORROW *

By ELLIOTT P JOSLIN, M D , F A C P , *Boston, Massachusetts*

The Hagedorn Era Today we are standing on the threshold of a new era in diabetes The Banting Era which we are now leaving was wonderful, and, even more, it was awe-inspiring During these last 14 years you and I have seen diabetics gain hope, food, strength, insulin has breathed life into their dry bones and they stand upon their feet, a mighty army Yet complications, although lessened in number and severity, persist and—I almost blush to admit it—diabetic coma is allowed to prowl about and decimate our diabetics by seizing the innocent, because undiagnosed, the ignorant and the careless Therefore we have good reason to welcome the discovery of protamine insulin The results with it in the hands of others and with my own patients are so distinctive that for me they amply suffice to name the new era in diabetes after its discoverer—the Hagedorn Era

It is not so much that with protamine insulin the blood sugar of the diabetic can be kept normal for the 24 hours, as it is that along with a normal blood sugar we can infer that there will be glycogen in the liver and muscles, a normal content of fat in the blood and freedom from acidosis, in short, a far more nearly normal bodily mechanism is made available for the diabetic But in a broader sense Dr Hagedorn's discovery is noteworthy He has made treatment with insulin safer and simpler and in so doing will multiply its use by practitioners and patients with consequent reduction in the complications and mortality of the disease Protamine insulin cannot help raising the standard of diabetic treatment throughout the world His discovery already is stimulating other discoveries in the technic of manufacture and administration of insulin The old insulin was so good that we were too satisfied with it There was too much of a *noli me tangere* idea about it That conception has now been broken by Dr Hagedorn and there will be a greater freedom in the world for various improvements in insulin medication Finally, and perhaps best of all, he has demonstrated so plainly that all can read its force that what we need most in medicine today is not more beds for our patients, but more brains for their better care

Not such a very great deal is yet known about protamine insulin There are the two articles from the Steno Memorial Hospital in Copenhagen and the George F Baker Clinic in Boston, in the January 18 number of the *Journal of the American Medical Association*, a monograph by Krarup, one of Hagedorn's pupils, and I have been privileged to see another This is to appear eventually in the *Journal of the American Medical Association*, and in it Hansen, another of Hagedorn's assistants, shows that with protamine

* Presented at the Detroit meeting of the American College of Physicians, March 2, 1936

insulin the large livers of diabetics will decrease in size. Consequently I will recount briefly our experience at the George F. Baker Clinic and supplement it with information I have gathered elsewhere.

Professor Charles H. Best of Toronto showed my patients a week ago today various lantern slides illustrating the effects of ordinary insulin and protamine insulin when given to depancreatized dogs. With one dose of ordinary insulin the dog excreted 25 grams of glucose in 24 hours, but with one dose of protamine insulin the amount excreted was 1 gram. In the one instance the blood sugar after eight hours began to rise to high levels, in the other it remained practically normal for the 24 hour period. I will show two slides, already published by our group in the *Journal of the American Medical Association*, which illustrate the comparison between the short and prolonged action of a single dose of insulin and protamine insulin when given to a normal individual and the treatment of a diabetic by the two methods with the abolition of peaks and valleys and the flattening of the blood sugar curves. (These and various other slides were demonstrated.) They illustrate by blood sugar curves (1) the high morning fasting blood sugar which so often characterizes the patient treated with old insulin and the normal rising blood sugar if treated by the protamine insulin, (2) the reduction of the blood sugar using one dose of old in the morning and new insulin at night, (3) the use of protamine insulin entirely, (4) the reduction of four doses of old insulin to two of the new and of two doses to one.

Eighty of our patients have been treated with protamine insulin since July 1935. Insulin for about one-fourth of these has been furnished us by Dr. Hagedorn and the remainder by the Eli Lilly Company. The action of the two has been similar. We have treated young and old, mild and severe cases, some of short, many of long duration, complicated and uncomplicated, including surgical, obstetrical, those with normal and those with high blood pressure and cases with infections. There have been no allergic reactions. Dr. Long this morning told me there had been one marked allergic reaction proved to be due to the protamine in one of his cases. There have been no abscesses despite the patients mixing the protamine with the insulin in their own homes. Reactions have occurred and recently we have observed more than at first because we have taken more liberties with the protamine insulin. I think only once has glucose been given intravenously for a reaction, but we have given up to about 50 grams by mouth. Reactions have appeared more than 14 hours after a dose and several times with children before the morning insulin. Reactions are less apt to occur with a correspondingly low blood sugar with protamine insulin than with regular insulin. Usually the reactions have been mild and with warning, but occasionally they have been quite severe and prolonged. The reason for this has been that we have used more insulin than necessary in an attempt to gain quick control of the glycosuria. To transfer from old to new insulin in a patient taking four doses requires from a week to ten days. At first one is often discouraged. As a rule we have used, as did

Hagedorn, old insulin before breakfast and new insulin before the evening meal, but of late more and more we have turned to new insulin morning and night. Hagedorn used a diet of carbohydrate 110, protein 73, fat 161 grams, with a large proportion of it at breakfast. We have used the more usual American diet of carbohydrate 150 to 175, protein 75, and fat 100 grams, and occasionally more carbohydrate, but it is possible that it would be wiser to keep at 150 grams carbohydrate, particularly as it is probable that with protamine insulin lipemia and large livers can be avoided.

Protamine is easily obtained for the new insulin. At first it was supposed that after the protamine was mixed with the insulin, the mixture would keep for only one or two days. We have found it effective after 14 days and Professor Best told me it remained stable, if placed in an ice chest, for a month, or, in other words, after making the mixture the contents of the bottle would be used up before it deteriorated. Professor Best also told me it was desirable to wait for 24 hours after mixing the insulin and protamine before administration to the patient. The vial should be shaken before withdrawing the mixture, and in cleaning the syringe, if alcohol is used for sterilization, the syringe should be allowed to dry before inserting it into the vial.

I believe many advances can be made in adjustments of diets and dosages of the old and new insulin to the needs of the patients. In our clinic we are concentrating again upon blood sugar tests, five daily, to determine how we can improve our methods and establish rules of procedure. I shall take pains at the meeting of the American Medical Association in Kansas City to arrange that one of the booths in the Diabetic Exhibit shall be devoted to protamine insulin and shall secure for it charts and ideas from several clinics and arrange that many different clinicians describe their experiences with it and the methods they have found most useful.

No patient who has begun the new insulin has asked to be returned to the old variety.*

One mother says, "Dr. Joslin, we had not had a real night's sleep since Ruthie had that bad reaction eight years ago, but now we sleep all night without a thought of Ruthie, and even in another room. She has had protamine insulin five months. You have no idea what it means to us. I would love to have you tell everybody."

And now I will take up certain features characteristic of diabetes of today.

Diabetes Is a Life-Long Disease I like to think of it as having begun with the tiniest baby in his bassinet and ending only with the last breath of life of the old man or woman. To be sure, we do not recognize the future diabetic in the nursery, and it is only in the last few months that I have realized that this also holds for the latter end of life. Indeed, only 63 per cent of my recent patients in Massachusetts when they died were classi-

* July 16, 1936. Correction of proof allows me to report that two of my patients have asked to be returned to the old insulin.

fied as diabetics. It is true 13 per cent had the word diabetes on the certificate, but escaped enumeration because other diseases took preference. Of the remainder who did not have the word diabetes on the certificate, 13 per cent would have been classified as diabetics if it had been placed there, but the remaining 11 per cent would not have been so classified. I object! At least our diabetics should have the recognition of dying *with* the disease, even all the more if they do not die *of* it.

Heredity Diabetes is an out and out hereditary disease. The individual who is to have it is born with it. To a considerable extent it is our fault that we do not appreciate the possibility of a baby developing the disease, and this is, first, because we have not studied sufficiently its family heredity, and second, because as yet you and I have not been bright enough to invent methods which will show the congenital tendency to the disease. We want to be able "to look into the seeds of time and say which grain will grow and which will not," which child will eventually become a diabetic, and which will be guaranteed to be free from the disease. That is a pretty *arbeit* for us all to work out. Someone discovered blood groupings. Why should not somebody discover a method by which the seeds of diabetes can be detected? Himsworth has recently made a praiseworthy attempt to solve it, although his conclusions that it is the result of a relatively low carbohydrate high fat diet I consider erroneous, first because he assumes that one can argue from mortality statistics to incidence statistics and second because he leaves out of account the all important age-of-onset factor and its relation to the age of the population.

I will show the slide which, to me, is the most convincing of the data assembled by Priscilla White as evidence of heredity of diabetes. Upon it you will note the incidence of the disease in the control population and in the diabetic population. But, most of all, I would point out the incidence in dissimilar twins contrasted with the overwhelmingly high incidence of diabetes in similar twins.

TABLE I

The Incidence of Diabetes in the Siblings of (1) Non-Diabetics, (2) Diabetics, (a) Dissimilar Twins and (b) Similar Twins

Type of population	Siblings number	Per cent diabetic
1 Non-diabetics	682	0.6
2 Diabetics	2385	5.0
a Dissimilar twins	16	12.0
b Similar twins	13	70.0

Age of Onset of Diabetes If we can assume that children are born with a tendency to the disease, when is it likely that the disease will become manifest? To this question we now have an answer, an almost uncanny answer, because of the similarity of onset by decades, no matter whether data are assembled in one clinic from time to time or in a group of clinics.

Suppose two diabetics marry and have a hundred children. These hundred children are fore-ordained and predestined to develop their diabetes according to a definite percentage for each decade from youth to extreme old age. Not all of the hundred will live to develop the disease, because many, as a matter of fact slightly more than half—56 per cent—will succumb to other causes, but the data are so definite that we can look ahead and form an idea of what percentage of these children will appear in each 10 years. This is shown in table 2.

TABLE II

Age of Onset of Diabetes—9853 Cases Male 4639 Female 5214

Decade	Per cent appearing in each decade	
	Males	Females
1	4.96	4.45
2	7.24	6.27
3	9.57	6.08
4	13.75	10.84
5	23.32	22.96
6	24.19	30.25
7	13.65	15.76
8	3.23	3.14
9	0.09	0.15
Totals	100.00	100.00

You will notice from the table based on the onset of diabetes that 5 per cent of the number will appear in the first decade, that the increase is slight in the second, incidentally, there is a definite rise at puberty, that the percentage doubles in the third, again doubles in the course of the fourth and fifth, rising in the sixth to a peak of 24 per cent for males and 30 per cent for females and then falls off rapidly in the seventh, and by the eighth is even less frequent than in the first. By the ninth it is so low there is practical immunity.

In any consideration of diabetes today, we must appreciate the ages at which diabetes is liable to break out and therefore concentrate our measures to prevent and diagnose it at such periods. I hope you notice the decade at which there is a change in the tide of susceptibility to diabetes, namely that the onset of the disease begins to fall in the seventh decade. Actually the peak is in the sixth decade and at about 55 years. This is very important for us all to bear in mind. If we did not do so, with the rising mortality from diabetes as years go on, we might be confused, just as the public is perplexed and does not understand that the number of cases of the disease is bound to increase until the average age at death of everybody has risen from its present level of 48.7 years (1930) to 55 years. The onset of diabetes in these later decades is not rising and the reason for the high mortality is that younger diabetics have ceased to die and have swelled the mortality for later years.

Duration of Diabetes Diabetes is a life-long disease, because it begins at birth and lasts until death, even though it may be unrecognized at either end of life. But it is also deserving this terminology, because when it becomes manifest, it lasts so long. For this statement I have good proof. Thus, of my 300 glycosuric doctors, the average duration of the disease among the 96 true diabetics who are dead was 11 years, and already among the 155 true diabetics living has reached more than 10 years, and I am sure that in this group there are many who have no intention of laying down their stethoscopes until they have lived out their full length of life. Indeed, of the fatal diabetics, my average diabetic doctor's age at death, 1929 to 1936, was 68.5 years as compared with non-diabetic doctors, 63 years, whereas among my living diabetic doctors the average age is now only 55 years. Think of what these doctors do after they develop diabetes. Who played a leading part in the discovery of pernicious anemia and received a Nobel prize?

My medal diabetics attest the long duration of the disease. Already there are at least 400 of these who have lived longer with the disease than was their lot according to insurance life expectancy tables. The average duration of 981 of my diabetics, who succumbed in the last five years, was 11 years, and as I contemplate the living patients, and especially the living children of whom there are in our group 188 whose diabetic life is over 10 years and of whom at least 53 have lived over 15 years since the onset of their diabetes in their childhood, I am sure that the average individual who develops the disease in 1936 or thereafter, will round out 20 years. For your encouragement, also, I will add that 10 times as many of my fatal cases in the last few years lived over 20 years as prior to 20 years ago. Finally, before 1914 the average age at death of my cases was 44 years, and now like the doctors, it is 63 years.

At the present moment the changing duration of diabetes is forced upon me in another way. In tracing the condition of patients with onset of diabetes under 40 years of age I find it extremely more expensive and time-consuming than hitherto because these patients live so long. When my cases died with an average duration of 5 years it was a simple matter to learn their whereabouts, but now it is extremely difficult, particularly in the case of the females, because they change their names. I suspect in a few years that it will be almost impossible to trace patients, as I have done hitherto, simply because they live so long.

Dr. Philip B. Matz of the Veterans Administration tells me that of 1243 living cases the average age at time of onset of the disease is 32.9 years and already the average duration is 9.1 years. There should be little difficulty in tracing the veterans, and they may furnish us ultimately with our most reliable diabetic statistics.

For the doctors this life-long duration of the diabetic carries a lesson. Doctors practice only about 30 years. When a doctor sees a diabetic patient, unless the doctor is very young, like most of you, the chances are that

his diabetics will outlive him. Here is a two-fold lesson. First of all, learn all you can from each diabetic so that you yourself can profit from the experiences which he goes through, and in the second place, remember that if you want a diabetic for your medical life, you must keep him alive. But how are you going to do it? The only way that anyone can keep a diabetic under observation over a period of years is to study more than the diabetic studies, to be able always to tell him something which he does not know and has not seen in the newspapers, to learn so much about the disease that you can detect his errors, to combine, either in yourself or those associated with you, every particle of knowledge which a student, a social worker, a dietitian, or a nurse has, so that you can help him, and then either teach him yourself or get these friends of yours to have that pleasure. To hold the patient you must be in touch with students and investigators or else be a student and investigator yourself, because otherwise your mind will not be open to the truth and profit by it. If your diabetic wanders to someone else, it is almost invariably your own fault if he does not come back to you. Diabetes is a life-long disease, and to treat it one must approach it from that point of view. The diabetic expects the advice and care which will protect him his entire life.

I count upon diabetes lasting as long as 20 years on the average, because I know you will learn control of the disease. How will you do it? For a discussion of this question I now ask your attention.

Control of Diabetes First of all, we all would like to go further and prevent it. That is more easily said than done because 25 per cent of the population in the United States, according to Priscilla White, are diabetic carriers. This does not mean that they will develop the disease, but they can transmit it if they marry an individual who is also a carrier. To me that vast number of carriers of diabetes, nearly 30,000,000, in our country, makes it preposterous to attempt to institute any extreme measures of prevention along eugenic lines. We can teach one diabetic not to marry another diabetic. We can talk about one diabetic family not marrying into another diabetic family, and all that is useful. However, we must remember that of our 100 children, born of two diabetic parents, only 56 will live long enough to develop the disease, and that if but one parent has the disease and the other is simply a carrier, the number of actual diabetics falls very rapidly. Indeed, if two diabetic carriers marry, the per cent of their children who actually will come down with the disease is only $\frac{1}{2}$ the expectation of 25—12.5 per cent. Of course, this is not an inconsiderable number, but it is very different from saying that 100 per cent of the children will develop the disease.

Furthermore, suppose that a few should develop the disease in the latter years of life. At that period we know it is quite amenable to control and the disease is not so terrible after all. Of course, I firmly believe that more bright men than fools are diabetic, and that there is enough of a pituitary element in the disease to make the diabetic outstanding in brains, as well as

in stature and precocious development I do not approve of two diabetics marrying and having children, but I will not go so far as to say that a diabetic should not marry a non-diabetic in a non-diabetic family and not have children

Heredity is important from another standpoint If we know there is a diabetic heredity in a family, we can seek to prevent those influences which are well recognized as favoring the onset of diabetes in that family The danger of obesity can be preached to parents and children and when we do that we are standing on sure ground because in the adult, obesity is a forerunner of the disease in an extraordinarily high percentage of the cases A good muscular development can be favored on the ground that, from experience with diabetic patients, we know without exercise the treatment of the disease is difficult I will not say that we should make suggestions about the quality of the diet It is safer to restrict the quantity Hims-worth would have us believe a high fat-low carbohydrate diet would predispose to diabetes Rabinowitch, from newspaper reports, appears to have found no diabetics among Esquimaux

Simpler Diagnostic Methods Easier methods in securing a diagnosis of diabetes should be adopted The most annoying group of glycosurics, as I have often said, is the group in which the diagnosis has not been cleared My group of this type is particularly large because it goes back before the days of routine blood sugar tests Even now it is too large, because so often patients do not want to come back for a glucose tolerance test In desperation a few weeks ago I decided to clear up as many patients as possible during the first visit For this purpose, I have given them 50 grams of glucose I tell them frankly that unless the test of the blood is positive in an hour one cannot draw conclusions from it But it was a satisfaction in one week to settle the diagnoses of four borderline cases in this manner, and I suspect that I shall follow up this principle still more Incidentally, think of the saving of costs to the patient and of work to the laboratory

Costs of Treatment Costs of treatment of diabetes constitute an important factor in the treatment of this disease which lasts for life We must consider these costs very seriously from the patient's point of view and from the doctor's point of view No patient should be deprived of treatment on account of the cost In order to protect the physician, arrangements must be made by which blood sugar tests can be done very reasonably or without cost We doctors in the hospital have a great advantage in this regard I feel that some permanent arrangement must be made by which doctors in private practice will be accorded the same relative ease in obtaining blood sugar tests from indigent patients and low income patients as are afforded doctors who happen to have a position on the staff of a hospital

Responsibility of Diabetics Responsibility for their own careers must be assumed more and more by the diabetic of today There are so many of them that unless they demonstrate that they can be independent, self-sus-

taining and make a success in life, a prejudice will arise against the whole group. I think diabetics are a superior race of individuals and therefore anything which can be done on their part to prove this and to show to all that they are not marching in a bonus parade to Washington is desirable. Each diabetic should hoe his own row.

Furthermore, each diabetic should make it his business in life to help another diabetic with encouragement, advice or financial assistance. Diabetics as a class are neither very rich nor very poor. Their interests are one. Realizing this, "Every man should help his fellow."

Treatment Diet The dietetic treatment of diabetes is so generally agreed upon today that consideration of it can be dismissed in a few words. Few there are who do not give their patients carbohydrate between 100 and 200 grams, protein between 60 and 90 grams, and fat enough in calories to enable the patient to maintain a weight which is normal or, in older patients, a trifle below the normal standard. It is not the details of diet and calories that are important, but rather the details of teaching the patient how to use the diet and calories. There are all sorts of methods, and each doctor finds out for himself what is most applicable to his own patients. Book knowledge will not do alone for these patients, they must be taught by illustration. They often learn most from one another. The class method of instruction is of enormous advantage. When I demonstrated to the class the reduction in the Benedict test which followed the use of four drops of the juice of one grape, I did more good than if I had talked about the dangers of eating grapes for an hour. Incidentally, after I did remove four drops of juice from the grape, the grape looked just as large as it did before, and that also impressed the class. I will pass over the diet, because I am sure it would be too much "coals to Newcastle" to speak of it here.

Exercise Exercise should be utilized even more than it is. I would like to show you certain slides which represent experiments conducted by my colleague, Alexander Marble*. All of these slides portray curves which show the effects of exercise as compared with rest with or without insulin fasting before breakfast. The secret lies in insulin. The normal individual and the mild diabetic have insulin, but the severe diabetic must buy it if he wishes to be benefited by exercise. Last year we gave our children insulin between 45 minutes and an hour before breakfast, and the children played more or less after it and thus brought their blood sugars down to a reasonable level before they started to eat.

Camps Our diabetic camps, the last two years, have taught us a great deal about the management of diabetes in children and suggested much which I am sure we can utilize with adults. We were able to keep a child at camp at approximately one-half to one-third of the cost that child would need if he stayed in the hospital. In these various camps we built laboratories, costing from \$200 to \$700, and we were able there to carry on the

* The paper has been accepted for publication in the *Archives of Internal Medicine*

treatment of the diabetic children more efficiently and more efficaciously than in the hospital. We had them all day in both places, but we could provide recreation, could supervise their diets more accurately, and give them more pleasure in the camps.

A Diabetic Boarding School The lesson we learned from the summer camps was that with our diminishing resources we must provide for the care of the diabetic children at other times of the year in similar fashion. This has led to the establishment of what I think is a new idea in the management of children, namely, a Diabetic Boarding School. For practical purposes this is what the Prendergast Preventorium amounts to so far as our diabetics are concerned. Originally at this Preventorium underprivileged children and undernourished children, but no children with tuberculosis, were taken. It is under the control of the Tuberculosis Society. Last year they agreed to take our children at \$10 a week, and we now have 10 children there, and they are supervised by a nurse skilled in their care and under the general direction of Dr. Priscilla White. These children are furnished their education by the City of Boston. Their board is paid either by them individually, or by the Welfare Societies—public or private. We are trying to centralize there, not only all the children—there are not so many of them—who need help away from home, but also other children who cannot be well-cared for at home. During the summer we had between 30 and 40 boys at this camp, but in the winter we have both boys and girls. When one of the children became ill he instantly was moved to the Deaconess Hospital. Camps and boarding schools for the uncomplicated cases—hospitals for emergencies. And now I want an inexpensive boarding house home—convalescent home—convalescent hospital for my older patients!

Wandering Diabetic Nurse for Adults Another idea has developed as a result of our work with children. Originally we employed the Wandering Diabetic Nurse only with our children and indeed Miss Winterbottom still acts as a Wandering Diabetic Nurse for them, but we have found lately that the children are doing so well that they require less of her time. You can hardly guess the type of patient she is helping this winter in their homes. Instead of our youngest patients, she is instructing, teaching and caring for our oldest—the old children above the age of 60 and 70 and even 80 years. Such patients one hesitates to move away from their home environment into a hospital. We have found that her services to these old people are most valuable and of course the cost to the patient is greatly reduced. I commend to you both the idea of a Diabetic Boarding School and the use of a Wandering Diabetic Nurse.

What Is a Wandering Diabetic Nurse? She is a composite of a nurse, a dietitian and a social worker. Few institutions and still fewer outpatient departments and almost no doctors can enlist three separate individuals to care for their diabetics, but each diabetic needs the services represented by these three professions, and the services must not be rendered routinely, but they must be specialized. The individual who assumes the

task of helping in diet, in nursing and in the social adjustments of these patients must be trained and indeed a specialist in diabetic work. Therefore, it is essential to combine all in one and therefore I attach great importance in any undertaking for improvement in the treatment of diabetes to the position of Wandering Diabetic Nurse.

Let me illustrate a little more in detail the desirability and, indeed, necessity, for such an individual. At the New England Deaconess Hospital we have 1200 diabetic admissions a year, but there are few hospitals that have 100 and there are a great many hospitals in smaller communities that do not have 25. When one divides up the total number of patients throughout the year, there is not work enough for three separate individuals and no nurse, dietitian or social worker will acquire experience enough individually to care for these patients properly. If we can center our instruction in one individual, gradually the hospital can develop specialized treatment so that not only its own patients will receive instruction along these different lines, but the instruction will be so good that doctors in the community will wish to take advantage of the service as well. I believe the endowment of a Wandering Diabetic Nurse in a hospital with 100 beds would be of immense advantage to the community, because her services could be drawn upon by physicians within the hospital's area in addition to the work she did actually in the hospital. There she could serve, not only in connection with the care of the diabetic patients in the institution, but also, because of her wide experience, could aid in teaching nurses the treatment of diabetes.

Diabetic Coma You and I know that it is very easy, even in a large hospital with hundreds of diabetics, to overlook cases of diabetic coma. We doctors overlook them. Nurses constantly overlook them and I regret to say that within the last 12 months we had one patient enter and die within 190 minutes of admission with diabetic coma. I am quite sure that such errors exist in other hospitals, and, in fact, I know and have personal cognizance of such errors. In our own case, experienced individuals were so absolutely positive that the patient had hypoglycemia that blood tests were delayed. I will say, however, that I really do not believe that the patient who died would have recovered, even if he had been treated for diabetic coma from the first minute he entered the institution. But my conscience would feel easier if he had been given every possible chance despite a blood sugar over 1000 milligrams, a CO_2 combining power of 2 volumes per cent and a blood pressure doubtfully obtained at 70.

Hospital Instruction Training in a hospital is desirable for practically all diabetics, and especially for those with small means. Gradually we have reduced the length of stay in the hospital from 30 days, prior to the discovery of insulin, to about 7 days, and I judge even less if we exclude cases with gangrene or infections of the feet. A year or two ago I advocated weekend hospital treatments for diabetics and still approve of it. Repeatedly we have patients come in on a Friday or Saturday and go to work

of a Monday. Sometimes they enter for more than one weekend. With lessening available funds to help needy patients, we are shortening more and more our hospital stays. Of course one cannot complete the treatment of a case or expect to do much more than to inaugurate treatment, but this alone is of great advantage and the balance of the treatment can be supervised through a Wandering Diabetic Nurse or by office visits. To secure success from a short hospital stay, the instruction must be concentrated. One cannot give long talks to patients. Recently we again changed our methods and we doctors, individually, give one talk of 30 to 45 minutes each day. This is supplemented by short classes or desk instruction or bed-side instruction by the teaching diabetic nurse in the hospital. More and more, however, I think we are emphasizing the help which one patient can give another. Indeed, over and over again I hear from patients that they will follow treatment, because of the complications which they saw other patients had in hospitals as a result of neglect of treatment. One can tell a patient to follow treatment and keep his feet clean, but the effect produced is nothing compared with seeing a patient who has his leg cut off, because he has neglected his diabetes and carelessly cut a corn. Therefore, just as we have made our money go farther with children by sending them to camps or to a diabetic boarding school and bringing into the hospital only the emergency cases, so now we are more and more bringing into the hospital diabetic cases for short periods and thus are making it possible to double and treble the number of patients who will have an opportunity to learn how to care for their diabetes.

Decision in Surgical Advice. Diabetics, and doctors as well, are dilatory in their decisions. Against our better judgment we are influenced by protests of the patients and delay operations which are indicated. Last year all of us, surgeons and doctors, consented to postpone an operation on an old man because of the faintest possible chance that his foot might heal. It cost the hospital and family at least \$600 and in the end, after months of considerable suffering, the operation was performed. For that same amount of money, 60 children could have had instruction and care of their diabetes and happiness for a week at a diabetic camp. When all the doctors and surgeons are unanimous in their opinion as to what is best to be done for the patient, the procedure should be carried out or the patient should be discharged to the treatment of another institution or doctor in whom he has more confidence.

Close Supervision of Diabetics. Diabetics require closer supervision. In an earlier portion of this paper I called attention to the fact that 10 times as many diabetics live 20 years, or more, now than they did prior to 1915. I did not add, however, that only one diabetic in eight of my last 900 to die, just prior to March 1935, reached this duration. It is perfectly possible, in my opinion, for diabetics on the average to live 20 or more years, but they will not do so by luck. If we want our diabetics to live, we must protect them from needless death, and these deaths today are primarily from

two causes, just as they have been for years past First, deaths from coma and second, deaths from infection, chiefly of the lower extremities There are other needless deaths which make so desirable a renewed effort to avoid them Tuberculosis relatively is far greater among diabetics than in the general population Thus Dr Howard F Root has shown that in Massachusetts it is more than 10 times as common in diabetic children as in the ordinary school child of similar age and two or three times as common in diabetics of all ages

Cancer is steadily increasing and it is of great interest in this connection that cancer of the pancreas is four to five times as frequently observed among diabetics as among non-diabetics This is a problem for continued study My opinion upon cancer may be biased because of proximity to the Palmer branch of the New England Deaconess Hospital in which so many cancer cases are treated

All are aware that coronary thrombosis and angina pectoris are conditions far more frequently observed in diabetics than in non-diabetics, but these are not so easily remedied by observation of the patient They are subjects for research On the other hand, coma, gangrene, osteomyelitis, tuberculosis and cancer are the complications which can be detected early and treated well What is the significance of all this, therefore, in our consideration of diabetes today? In my opinion, we must change our method of treatment Hitherto I have not asked patients to come back regularly for observation, but beginning January 1, 1936, I am telling each patient, specifically young and old, recent case and old case, that he should keep under the supervision of some doctor and be looked over as a routine at least every three months more or less, according to the case I intend to give each patient, in the letter I send him after his visit or on a card, a statement that he should see some doctor at least within three months after his visit to me Most doctors do not like to ask patients to come back for fear they will be accused of grasping for money I know that many of us who see patients for other doctors hesitate to ask patients to come back or even to communicate with them, but I believe it is possible that a more aggressive attitude can be adopted and in doing so the family doctor as well as the patient can be protected At least, I am willing to try an out and out experiment and risk the opprobrium which it may arouse

Coma still causes more deaths in diabetes than it should It is true that the mortality has fallen from 64 per cent (among 325 of my deaths) prior to May 31, 1914, to 6 per cent (among my 981 deaths) ending in March 1935 These figures apply to deaths both in and outside the hospital By and large, however, throughout the country, I suspect that the mortality from coma is still between 10 and 20 per cent How can this be remedied? In general by education of the patient and insistence upon his keeping in touch with his physician and always reporting immediately when any unusual symptoms occur The opportunity for improvement does not rest alone with the patient and with the general practitioner I

know from our own bitter experience that treatment in the hospital can improve. Cases of coma are still unrecognized or confused with other states. My colleague, Dr Root, points out that errors in diagnosis are always to be expected in moribund patients, but he too feels, as I do, that this is no excuse for the delays which sometimes arise, and I fear far more frequently than is generally believed, before the diagnosis of diabetic coma is made after the patient reaches the hospital.

A Coma Drill A coma drill in a hospital is essential, just as is a fire drill. Neglect to have one I think will surely result in unnecessary damage to the patient and the reputation of the hospital. It is easy enough to send a specimen of the blood to the technicians in the laboratory by day, but at midnight and in the early morning hours, when technicians are not available and house officers are out of practice in determination of blood sugars, CO_2 values and non-protein nitrogens, it is very easy indeed for mistakes in analysis to arise. I suggest for your consideration the establishment of a diabetic coma drill in your hospital with records to be kept as to how long it takes to secure blood and make a diagnosis. Minutes count in the treatment of diabetic coma or hypoglycemia and arrangements should be perfected, just as I am sure you already have arrangements perfected for the reception of a coma case into the wards.

Follow-Up of Discharged Cases The sequel of the old man or woman whose toe or leg has been removed, because of diabetic infection or gangrene, has not been encouraging. I hesitate to state the few years which such patients live. My colleague, Dr Root, has been much interested in this, particularly because of his association with Dr McKittrick in compiling the monograph on "Diabetic Surgery." Recently Dr Root has arranged that once a week the relatives of the patients with lesions of the legs should see him for a talk so that they could be prepared for the care of their parents, brother or sister, wife or husband, when discharged. This has proved to be quite worth while. The conference has taken place in the early evening when relatives visit the patients.

Dr Root has also instituted another forward step in that the Wandering Diabetic Nurse sees the patients with a lesion of the lower extremities within 10 days after discharge. The follow-up of this special group of cases has also proved well worth while. As a rule, patients coming with lesions of the lower extremities are patients who are poor. They need supervision at home. We need more organization in their care.

Insulin Insulin gave us a new diabetic to treat. Even now we hardly have begun to realize its benefits. I am sure they are far more than those represented by prolongation of life or reduction of complications. The spirit, as well as the body of the diabetic, has been protected. Today treatment with insulin is so well understood that it is almost automatic and if a doctor is really interested and will read his medical journals or even the standard textbooks, he will not go far astray. No longer do we try to give one large dose (I am speaking of regular insulin, not protamine insulin)

and expose the patients to reactions when two doses will be more efficacious. If three doses are needed, often the third can be taken conveniently on retiring so that an approach to a normal blood sugar can be secured on waking. We all know that insulin works and that if unusual dosage is necessary there is a reason for it and that it is for us to find the reason. Generally the reason lies in an infection, open or concealed. Often it is associated with other glandular trouble. Seldom it is the result of faulty administration, but quite commonly a sequence of a poorly-balanced diet and a previously neglected diabetes. Mrs. St. C. had a severe reaction when the site of her injection was changed. She is an insulin resistant case, taking 400 to 500 units. It is a wonderful step forward that now we realize that insulin will act favorably upon the standard case of diabetes.

None of us are unmindful of errors with insulin, in measuring dosage, in methods of administration, reduced efficiency because of insulin lumps and of the atrophies occasionally developing without known cause. Most of all, however, the dangers of hypoglycemia have been foremost in our thoughts. These have been greater of late than formerly because today with insulin the diabetic is so well that he wanders farther afield and so is under less close supervision.

The Rôle of the Liver and the Interrelation of the Ductless Glands in Diabetes. The liver and the ductless glands are bee hives of experimental activity in diabetes today. That the excessive deposition of fat in the liver can be prevented by choline is a triumph attained by Best and his co-workers in Toronto. The next speaker, Dr. C. N. H. Long, will tell you of the diabetic wonders achieved by the experiments of Houssay upon the pituitary and the new operations involving not only the pituitary, but also the medulla and cortex of the adrenal, which he, in association with his colleague, Francis Lukens, has devised, executed and interpreted. Indeed, Dr. Long's paper will give you a far better idea than mine of what to expect in the Diabetes of Tomorrow.

CLINICAL ASPECTS OF CIRCULATORY DYNAMICS IN ARTERIAL HYPERTENSION *

By ARTHUR R ELLIOTT, M D , L L D , F A C P , *Chicago, Illinois*

WE know that of patients who have persistent high blood pressure a considerable percentage—estimated by some authorities to be as high as 25 per cent—will die of causes that have no bearing whatsoever on their hypertension. The remainder will succumb through development of some condition directly attributable to the prolonged circulatory strain. A small percentage will die of progressive renal insufficiency, resulting from arteriolar changes in the kidney or more likely from progression of an unrecognized obscure nephritis. A larger number will develop cerebral accidents, the so-called hypertensive encephalopathies. The remainder, predominantly the largest group of hypertension casualties, die of cardiac failure. It is with this latter aspect of the ultimate consequences of arterial hypertension that the present discussion is concerned.

Certain facts or inferences emerge from practical experience with the run of cases of high blood pressure. For example it would appear that patients who have a marked hereditary bias toward vascular pathology usually sustain the strain of elevated pressure for longer periods than those without such a background. This is difficult to explain unless it be that certain constitutional resistances enter into their tissue make-up as provision against this inherited liability, and so insure their survival, or perhaps it may be because these individuals develop high pressure earlier in life and more gradually than do others. Another observation common to all experience is that high blood pressure developed in association with or in consequence of certain other disorders may be viewed more tolerantly than when it emerges as a single symptom. For example when it exists in common with diabetes, hyperthyroidism, chronic anemia, uterine fibroids, prostatism, etc., it rarely is as malignant in its effects, and moreover tends to share in the beneficial influence of therapeutic control of its associate. In passing it should be noted that exactly the opposite is true when hypertension results from nephritis. Another well-tolerated form of hypertension is the elevated systolic pressure resulting as a compensatory response in aortic atherosclerosis. This is compatible with long life and reasonable efficiency. I get the impression from a review of my experience that what has been called the neurogenic variety of hypertension has a milder prognosis although usually a more stormy symptomatic course than is true of other forms. The blood pressure in such instances is particularly unstable, being subject to wide fluctuations, so that there is more easement to the cardiac and vascular strain than is available in other cases. These are the

* Presented at the Detroit meeting of the American College of Physicians, March 6, 1936

patients who derive the greatest benefit from appropriate personal hygiene and especially from bed-rest and hospitalization. Other things being equal it is a fact that marked decline in average pressures induced by rest either alone or combined with simple sedative medication foretells a better prognosis. To complete these brief notes on prognosis in arterial hypertension I should revert to the well known fact that the outlook is in all ways more favorable among women than men. They live longer and a higher percentage of them die of causes not connected with their hypertension. This strange fact is not because women do not have pressures as high as those of men. Its significance may lie in some resistance-provision in the female circulatory structures inherent in their biology as a survival factor or in the less strenuous life of the average woman as compared with the average man. Moreover another factor may enter in and that is the influence of the menopause which slows down many women and may thereby prove a buffer mechanism.

This brief reference to certain considerations having bearing on the prognostics of hypertension yields the impression that incidental factors and influences that tend to moderate the persistency and severity of the strain prolong the ability of the heart and vessels to carry the load and that the heart is preponderantly the determinant of the prognosis. The mechanico-pathology of the heart and how it comes about is therefore the great concern and interest in the clinical study of blood pressure.

I need not labor the point that patients coming under observation for the first time with very high pressures and evidences of strain in the cardiovascular apparatus may survive for years even in the face of conditions that appear absolutely to preclude such a prospect. This fact stands as a tribute to the extraordinary capacity of the heart to tolerate profound maladjustments in the dynamics of the circulation. About the only thing, generally speaking, that appears to interfere with this compromise is the presence of coronary artery disease, especially coronary occlusion with infarction of the myocardium, but in exceptional cases even this development may not prove an intolerable handicap.

The work of the heart depends not only on the peripheral resistance but also upon the amount of blood its chambers discharge. Cardiac output has been the subject of study by several investigators but for various reasons no uniformity of opinion as to the reliability of the results secured has been reached. For what they are worth the significance of data accumulated in arterial hypertension appears to prove that basal cardiac output remains unaltered so long as congestive heart failure has not supervened. The findings, imperfect as they may be, yield the general impression that the high pressures of chronic hypertension are neither established nor maintained by an increase in the volume of blood discharged by the ventricle. These findings rather support the conclusion that the exaggerated pressures and consequent increase in heart work are due to increased peripheral resistance re-

sulting from precapillary constriction which is the characteristic feature of hypertension

Inasmuch as the work done by the heart pump is almost entirely spent in overcoming resistance, the fall of pressure from aorta to periphery being extreme, it follows inevitably that the capacity of the ventricle to maintain efficiency in the face of permanent and steadily increasing resistance must in time become exhausted. That this event is so long postponed may be because coronary blood flow is chiefly dependent on aortic pressure, any increase of which results in free flushing of the myocardium. This is a matter of pressure rather than of cardiac output or heart rate which influence the coronary circulation far less. An added beneficial effect on myocardial nutrition may result from the fuller clearance of the vascular stream bed resulting from the slow heart rate and prolonged diastole present during much of the clinical course. As an offset to this advantage stands the undoubted fact that the coronary arteries are in some manner detrimentally affected by continuous increase in blood pressures so that coronary obstruction develops more frequently in these subjects than in any others.

The ultimate effect upon the coronary vessels even without the dramatic event of occlusion is to produce in the majority of cases varying degrees of narrowing of their caliber from sclerosis, often with secondary fibrotic alterations in the muscle fibers throughout a considerable area of the heart wall. That these scarrings are not more frequently detected is perhaps because the gross-pathologist is apt to confine his inspection of the myocardium to a search for infarctions and overlooks less obvious defects. This point has been emphasized by some pathologists, notably by Klotz. The matter is important because we are gradually swinging around to the position that it is not work exhaustion per se that causes the hypertensive heart to fail but interference with the chemical exchanges in the myocardium through progressive restriction of the coronary blood supply. Lowering of the systemic blood pressure cannot necessarily be taken as evidence for or against the existence of widespread coronary disease. There exists no constant ratio as between height of blood pressure and myocardial dysfunction. It is not exceptional to see blood pressure maintained at or near its usual level after coronary occlusion, and many patients retain heightened pressures despite extreme degrees of myocardial failure even up to death itself. It was emphasized years ago by Norris that the last ounce of reserve power of the heart may be put forth in maintaining blood pressure levels and the heart muscle be actually at the point of final failure notwithstanding a pressure well above normal. It is a mistake then to expect necessarily a fall in blood pressure with cardiac failure no matter how induced. This may be because pressures are much more easily influenced by changes in the caliber of the peripheral arterioles than by alterations in cardiac output, and peripheral constriction may be at such a high point that even a small output may suffice to maintain pressures at an abnormal level.

In our zeal to interpret the importance of the heart and the larger vessels of the distributing system it should not be forgotten that these more obvious phenomena are but means to the end that an adequate capillary flow be constantly maintained. This is a point much neglected and yet the picture is not complete if we do not take into account what goes on in the vascular channel distal to the heart and aorta. It is well to remind ourselves that the dynamics of the circulation are not entirely a function of the heart pump. The initial propulsion of the blood appears to be its sole and only function, in short, as Harrington Sainsbury puts it, the heart is a "power chamber." After the cardiac systole is completed diffusion of the blood throughout the circulatory tree becomes the business of the arteries. Inasmuch as systole is shorter in time than diastole it might appear that the arteries absorb a larger share of the work of circulatory movement than does the heart. If there be truth in this assumption then what goes on in the arteries in hypertension becomes of great importance to the fate of these patients. First of all it is well known that the aorta is essentially an elastic tube cunningly devised to receive the oncoming blood from the heart with, as it were, "open arms." After distention follows recoil, allowing the "run off" into the smaller vessels to continue during diastole. These lesser vessels possess little elasticity and though heavily endowed with muscular equipment they have little propulsive power. They are but smooth channels allowing flow without friction or loss of head until the precapillary bed is reached where the stream slows down and pressure sharply declines. There is comparatively small reservoir capacity in the arteries. Such as there is depends on their elastic stretch and this, except in the aorta, is not considerable. Their maximum extensibility lies slightly above the usual systolic pressure in health. Above that limit the cubic enlargement of the arteries is less and less as pressure rises and the heart responds to its increasing labors. It is a mistake to assume that the compensatory hypermyotrophy that thickens and strengthens the heart wall does not affect the arteries in like manner. This is shown in cross sections of these vessels and to the palpating finger they seem rigid and taut. This compensatory reinforcement by the arteries offers a valuable element of collaboration to the heart in carrying on its task in the face of increasing resistance. How important this ancillary action may be is revealed in due time. The unfortunate predicament of the arteries in this circumstance is to be caught between the upper and nether millstones—the strongly acting hypertrophied heart on the one hand and the constricted precapillary bed on the other. During the sthenic or fully compensated stage of hypertension the arteries are observed to be taut or rigid but they are not tortuous. Under the excitant effect of persistent internal overpressure molecular degenerative changes in the vessel walls result and progress until what Norris has designated a "break in vascular compensation" supervenes. This is revealed by a rather rapidly developed tortuosity and relaxation of accessible arteries. We may palpate it best in the brachial and femoral arteries and see it strikingly in the retinal field. The

effect of this relaxation of general arterial tone upon the heart proves unfortunate because thereby is shifted upon that already overworked organ an added burden. For years I have watchfully observed this sequence of arterial events and find reason to regard it as extremely significant. The advent of arterial dilatation often proves to be a forerunner to the development of weakness and failure of the ventricle with the phenomenon of congestive heart failure.

Another arterial phenomenon that will profitably repay study in hypertension is the pulse rate. During the greater part of the clinical course the pulse rate is not increased, indeed it is often slower than normal. In experimental work it has been found that when the heart rate is slowed not only is the blood given a longer time in which to pass the peripheral narrows but the longer diastole allows a more complete filling of the ventricle during its relaxation, thus offsetting the effect of slow rate on cardiac output. Another consideration that may render the slow heart rate of decided benefit is the theoretical deduction based on the known laws of oxygen diffusion that the enlarged heart with its thickened muscle should require a longer time between beats to recover than does the normal sized organ. Since there is no acceleration of rate in most instances of hypertension and little evidence exists of increased stroke volume, an increased minute flow might be assumed. Many workers employing various methods have studied this phase and failed to demonstrate any increase in minute volume flow—indeed it may even be below normal limits. Leaving aside physiologic explanations, which as yet appear to be in a confused state, the clinical fact stands out clearly that a slow pulse rate in hypertension is the best assurance we have of adequate reserve on the part of the heart pump. With increase in heart rate, which in time becomes inevitable, abbreviation of diastole diminishes the inflow quantity of blood thus reducing the amount of blood ejected during systole. Not only does the general circulation decline in proportion to this handicap but, still more important to the patient, the coronary circulation is detrimentally affected by decline in aortic outflow. The thickened muscle fiber of the heart is a decided asset in overcoming arterial resistance but at the same time it suffers from a chemical disadvantage—any decline in coronary flow laying it open to the accumulation of oxygen lack which the myocardium is much less tolerant of than is skeletal muscle. In this manner there comes about with the advent of rapid heart rate a vicious circle tending eventually to produce congestive failure with its train of disadvantages.

Some controversy has existed as to whether the systolic or the diastolic pressure constitutes the breaking strain upon the ventricle. Determination of the time course of the pressure curve in the ventricle shows that no blood is expelled until the maximum tension is developed. During the expulsion of blood into the aorta the pressure in the ventricle remains nearly constant, the curve showing a flat top. This would go to show that the greater part of the work done by the heart muscle is expended in raising the pressure of the blood to the diastolic level and would give that factor the greater im-

portance This seems to be in keeping with clinical experience, for we know that a continuously high diastolic pressure is not well tolerated although per contra a very high systolic pressure may be carried for years without evidence of cardiac exhaustion provided the diastolic pressure remain low This gives the pulse pressure significance merely as a rough index of the mass movement of the blood without any fixed prognostic importance During the stage of adequate compensation the circulation to all appearances is carried on normally In the main the elevated systolic pressure may be considered as evidence of relatively normal heart power and normal blood flow Yet we must not assume that volume flow runs proportional to blood pressure, for the factor of peripheral resistance must be taken into account Neither is it, as already pointed out, correct to infer that an abnormally high blood pressure constitutes an indication of adequate cardiac power Even with the signs of congestive failure present throughout the body blood pressure may still remain considerably above normal Indeed it may be said that there are no definite rules whereby we are altogether safe in judging the import of either a rise or fall of blood pressure In patients seriously embarrassed a rise of pressure may denote restoration of compensation and general improvement, whereas with certain others it may prove unfavorable, implying the advent of uremia On the other hand a fall in pressure levels may prove a favorable indication, signifying lessened toxemia and diminished peripheral constriction Heightened pressure is consequently not necessarily an index of good cardiac response nor is a lowering pressure portentous of approaching cardiac exhaustion The claim that arterial hypertension is a conservative mechanism rendered necessary to maintain an effective working of the organs, especially of the kidneys, does not receive striking confirmation from clinical observation, for many patients appear to profit greatly and suffer no decline in renal elimination when a high blood pressure is lowered by effective treatment To place implicit trust in instrumental readings as an index of progress or for prognosis in any given case is to invite error The patient's general condition and evidence of well-being, his range of efficiency, the presence or absence of well attested signs of circulatory embarrassment constitute better grounds on which to form a judgment than information procurable from blood pressure figures alone with theoretical deductions therefrom

DEXTROCARDIA IN CHILDREN ~

By HENRY A. REISMAN, M.D., F.A.C.P., *Jamaica, N. Y.*

THE term dextrocardia should be employed to designate all instances in which the heart is found in the right side of the thorax. If thus employed, the term loses its connotation as a mere anatomical curiosity, and the study of the etiological types of dextrocardia assumes its rightful importance.

The present discussion of dextrocardia in children is illustrated by reports of eight cases. During the course of a study of tuberculosis in school children, in which the author has participated, roentgenograms of the chests of 11,253 children have been made. In this series three cases of dextrocardia have been found, each illustrating a different etiological factor. Another case in which dextrocardia was caused by a marked scoliosis has not been included in this report. Five more cases which have been encountered by the author among children are briefly summarized.

CASE REPORTS

Case 1 A. Z., male, aged 8 (of the tuberculosis research group), referred for physical examination because dextrocardia was found in the roentgenogram. There were no complaints. He is the only child, and the family history is negative. Birth was normal with no cyanosis. He sat alone and had his first tooth at six months, walked and talked at 14 months. He has had measles and scarlet fever. Mantoux negative.

Physical examination corroborated the roentgenographic findings. The cardiac dullness and impulses were on the right side, and the liver dullness on the left. There was no evidence of any pathologic cause for the dextrocardia on either roentgenographic or physical examination. Electrocardiogram showed mirror image inversion of normal Lead I (figures 1 and 2).

Diagnosis Congenital dextrocardia with situs inversus.

Comment The occurrence of cardiac misplacement in conjunction with transposition of viscera has long been known. The first reported observation is credited to Petrus Servius² in Rome in 1643. It was also reported in Paris in 1650² in the man who was executed for the murder of the Duke of Beaufort, as related by Guy Patin, and later reported in London in 1674. Its incidence has been variously estimated. It is said to be approximately 1 in 10,000. The difficulty in determining the incidence accurately is obvious. However, one case in over 11,000 is here reported. Moffet and Neuhoﬀ³ reviewed the literature from the year 1649 to 1915 and were able to find only 126 reported cases of true congenital dextrocardia.

A second case of congenital dextrocardia with situs inversus was found

* Received for publication August 10, 1935.

FIG 1 Case 1 A Z, male, aged 8 years Congenital dextrocardia with situs inversus

Fig 2 Case 1 A Z, male, aged 8 years Mirror image inversion of normal Lead I

in a child referred to our chest clinic (Pediatric Department, New York Post Graduate Medical School and Hospital)

Case 2 P. M., female, aged 2½ years The chief complaint was of a chronic cough since birth and of frequent colds

Physical Findings 1 Dextrocardia, heart sounds normal, no symptoms referable to the heart 2 Numerous coarse and fine râles on inspiration on both sides posteriorly with some expiratory coarse râles 3 Throat congested, marked post-nasal drip, tonsils enlarged and infected

Laboratory Findings Roentgen-ray Chest 1 Dextrocardia with visceral transposition 2 Central pneumonic infiltration Sinuses Pansinusitis Mantoux Negative Electrocardiogram Mirror image inversion of normal Lead I

Diagnosis 1 Chronic bronchitis 2 Central pneumonitis 3 Pansinusitis 4 Congenital mirror picture dextrocardia with situs inversus

Comment As early as 1749 dextrocardia was divided into congenital and acquired groups Nagel⁴ divided the congenital dextrocardias into two main groups 1 True mirror picture congenital dextrocardia, 2 congenital dextrocardia due to arrest of development

The exact nature of the pathogenesis of these groups is still not clearly understood

In true mirror picture dextrocardia the heart is reversed or transposed upon itself, coming to lie on the right side with the relationship of the various structures of the heart to each other remaining both physiologically and anatomically unchanged The apex points to the right The apex beat is palpated near the right mammary line and is formed by what is normally the left ventricle, presenting a true mirror picture of the heart This type of dextrocardia is usually associated with transposition of the other organs or viscera Congenital mirror picture dextrocardia without transposition of the other viscera (isolated dextrocardia) does occur, but it is exceedingly rare, in which event it is to be differentiated from dextrocardia due to arrest of development It is possible to have all kinds of combinations of transposition of the viscera Abernethy⁵ in 1793 reported the case of a female infant, 10 months of age, in which the heart was on the right side, the liver in the midline with the rest of the organs in their normal positions Royer and Wilson⁶ report the case of a boy, aged six years, found to have complete transposition of all viscera except the heart which was in its normal position Even the lungs were included in the transposition The three-lobed lung was on the left side and the two-lobed on the right

In congenital dextrocardia due to arrest of development the heart is said to retain the position occupied by it during the early stages of embryonic life, because of an arrest of development There is no transposition of other viscera The apex points downward and is formed by the right ventricle As a result of this arrest of development there is not only a dextrocardia but also grave and complex anomalies of the heart associated with it, such as transposition of the aorta and pulmonary artery and complete

defect of the cardiac septa, as in Wenner's ⁷ case. There may be many possible combinations of defects, from the slightest to the gravest, either of the large vessels themselves, of the communication between the large vessels and the heart, or of the heart itself. In this type there is usually marked cyanosis, and the prognosis is grave. In uncomplicated mirror picture dextrocardia the sounds are normal, there is no cyanosis or anatomical interference with the heart function, and the electrocardiogram will show the characteristic findings—a mirror image inversion of normal Lead I. On the other hand in dextrocardia due to arrest of development there is only a right sided preponderance.

Case 3 W F, male, aged 10 years

Past History Normal delivery, cyanosis since birth, feeding was difficult. Mother says that as an infant he turned very blue whenever he cried or ate. Had seven attacks of purulent otitis media in the first year of life and was considered "delicate." Mother was told at three months of age that child had a dextrocardia, and at five years of age was told that he had a murmur in addition to the dextro-

FIG 3 *Case 3* W F, male, aged 10 years. Congenital picture dextrocardia with situs inversus. Congenital heart disease, probably septal defect.

cardia Had bronchopneumonia at seven years of age, which was associated with marked cyanosis Measles at eight years, no complications In February 1935 had left lower lobar pneumonia Temperature seldom reached 101° by rectum, and pulse was between 50 and 60 There was marked cyanosis, and resolution was delayed A month later he had a second attack of pneumonia

Physical Examination Underdeveloped, pale youngster Cyanosis of lips and fingertips, no clubbing Heart impulse felt 11 cm to the right of the midline There was a harsh systolic murmur heard at the base and over the precardium There was no thrill Lungs were clear Liver and spleen not palpable

Fluoroscopic Examination A P View Heart seen to the right of the midline with general cardiac enlargement First Oblique (right shoulder to screen) showed enlargement of left ventricle Second Oblique (left shoulder to screen) showed the retro-cardiac space clear

Roentgen-ray (figure 3) revealed 1 Dextrocardia with situs inversus 2 Enlarged and ovoid type of heart 3 Accentuated pulmonary markings

Electrocardiogram 1 Normal sinus rhythm 2 Normal A V conduction time with occasional sino-auricular block 3 Right axis deviation of the Q R S 4 Q R S low voltage and notched 5 Mirror image inversion of normal Lead I 6 P-wave inverted in all three leads 7 Abnormal T-wave in Lead I Conclusion In addition to a mirror picture dextrocardia these abnormalities indicate myocardial disease with probably some disturbance of conduction through the bundle of His, as indicated by number 4

Diagnosis 1 Congenital dextrocardia with situs inversus 2 Congenital heart disease, probably some septal defect with cardiac enlargement 3 Myocardial disease in region of the bundle of His

Comment The roentgen-ray and the electrocardiogram undoubtedly prove that the dextrocardia is of the true mirror picture type If this case were seen in the first month of life it would be apt to be confused with dextrocardia due to an arrest of development because of the marked cyanosis The roentgen-ray alone would be sufficient to aid in differentiation in that it would reveal the situs inversus which is always associated with true mirror picture dextrocardia The congenital heart lesion (septal defect) which is superimposed upon a true congenital dextrocardia easily accounts for the cyanosis The patient also has myocardial degeneration probably involving the bundle of His, as shown by the electrocardiogram, which may account for the very slow pulse during his attack of pneumonia Moffet and Neuhoﬀ² report a true congenital dextrocardia with situs inversus also associated with a patent inter-ventricular septum with cyanosis

The classification of congenital dextrocardia is not sufficiently inclusive from a practical standpoint This is exemplified in the following two cases which are undoubtedly congenital but have all the characteristics of the acquired type

Case 4 M R male, aged 6 years (of the tuberculosis research group), was referred for physical examination because the heart was found on the right side There were no complaints, except for an occasional cough The appetite was good The delivery was by Caesarian section, and the birth weight was eight pounds Development was normal both physiologically and physically He had measles, scarlet fever and whooping cough There were no subjective symptoms referable

to the dextrocardia or to the condition causing it. Roentgen-ray (figure 4) revealed a definite diaphragmatic eventration with a dextrocardia.

Physical Examination The apex impulse was in the right mammary line with the cardiac dullness on the right side. There was no evidence of transposition of other viscera. Normal liver dullness was elicited on the right side. There was definite increase in resonance with diminished respiratory sounds at the left base. Both child and parents were uncooperative. They disappeared when a fluoroscopy with barium was prepared and repeatedly broke appointments for both a fluoroscopic and electrocardiographic examination. Mantoux test was positive.

Diagnosis Dextrocardia secondary to eventration of diaphragm.

Comment Baynes-Jones⁸ tabulated 45 cases of eventration of the diaphragm from the literature. The great majority occurred in males. Three

FIG 4 Case 4 M R, male, aged 6 years. Dextrocardia secondary to eventration of the diaphragm.

were right-sided lesions, while 42 were on the left side. He states "In eventration the diaphragm is greatly thinned as well as distended, and there is no solution of its continuity. In this essential respect the condition is different from hernia of the diaphragm which, whether true or false depending upon the presence or absence of the hernial sac, consists of a localized opening in the sheet of the diaphragm through which the abdominal viscera pass into the thoracic cavity."

Blackford and Booth⁹ in 1932 reported a case of dextrocardia secondary to eventration of the diaphragm identical to the one here reported. The electrocardiogram was normal. Landis¹⁰ says concerning eventration "That eventration is a congenital abnormality is apparent. As the condition is congenital both the thoracic and abdominal viscera accommodate themselves to the defect, and as a result there are no symptoms." That the condition is not always congenital, however, is evidenced by Hedblom's¹¹ case of dextrocardia secondary to eventration of the diaphragm presumably due to neuritis of the phrenic nerve with evidence of neuritis elsewhere in the extremities. Both the diaphragm and the heart eventually resumed their normal position. Landis further states "The condition may be suspected on physical examination, but in most instances it is discovered as a result of the roentgen-ray examination or at the autopsy table." Of physical signs he says "In left-sided cases the most striking sign is the abnormally large area of tympany both anteriorly and posteriorly. Owing to the large area of tympany the condition most likely to simulate eventration is pneumothorax or congenital hernia. Among the more unusual conditions are large basal cavity and subphrenic abscess producing gas. As eventration never gives rise to any disturbance and is usually an accidental discovery it requires no treatment." Although eventration is considered a harmless condition it may, however, have very serious consequences. Blackford and Booth⁹ quote a case that ended fatally. A young woman had been healthy until several months' pregnant. In the examination because of the abdominal symptoms which developed at that time it was found that she had an eventration on the left side with the heart displaced to the right. She would not consent to an abortion, and during labor which was premature a complete rupture of the diaphragm and death occurred. It is conceivable, therefore, that any condition, such as whooping cough, which could produce a marked increase in intra-abdominal pressure might cause a rupture of the weakened diaphragm. Similarly it is possible that eventration may also be acquired from a congenitally weak diaphragm.

Case 5 L. D., colored female, aged 1½ years, admitted 9/10/34 on Pediatric Service Jamaica Hospital. Died 9/11/34.

Past History Patient well until day before admission when she refused nourishment and vomited the little she took. No bowel movement in the last 36 hours. Two enemas given daily before admission. First yielded some fecal material, second returned clear. Has vomited all food taken day of admission. There was no fever. She received nothing but water in the 24 hours prior to admission. Later additional his-

tory revealed that only liquid food was given the child since birth, and that just prior to the onset the child was given ham and eggs

Physical examination revealed 1 Acetone odor to breath 2 Malnutrition 3 Heart sounds and impulses on the right side 4 Some diminution of breath sounds on the left side with dullness on percussion in the lower part of the chest 5 Marked distention with dullness on percussion over upper left quadrant Remainder of abdomen not distended A nasal tube was passed and 17 ounces of clear fluid were obtained following which distention disappeared 6 Albuminuria 7 Leukocytosis of 15,600 with 74 per cent polynuclear cells

FIG 5 Case 5 L D, female, colored, aged $1\frac{1}{2}$ years Dextrocardia secondary to congenital diaphragmatic hernia

Roentgenogram (flat plate of abdomen and chest) (figure 5) 1 Dextrocardia 2 Hernia of left diaphragm

Diagnosis Congenital diaphragmatic hernia with secondary dextrocardia

The general condition of the child became rapidly worse. It was decided to operate without delay. At operation the stomach was found to be rotated about one inch proximal to the pylorus. The stomach was greatly distended and displaced

upward into the left thoracic cavity together with the transverse colon, spleen and coils of small intestine. The diaphragm was totally absent on left side, there being only reflections of peritoneum about one-half inch wide on either side with some muscular fibers around central dome. The child died several hours after the operation.

Autopsy corroborated the operative findings. 1 Massive collapse of left lung 2 Displacement of heart to the right 3 Fatty degeneration of liver 4 Herniation of left diaphragm 5 Repair of left diaphragmatic leaf

This is undoubtedly a congenital hernia (false) because of the almost complete absence of the diaphragm, the absence of a history of violent injury, and evidence that the collapse of the lung had existed for a long period.

Comment. Diaphragmatic hernias are classified either as congenital or acquired, and are further classified as true or false depending upon the presence or absence of a sac. The congenital hernia is due to incomplete development of the diaphragm. The acquired hernia develops after birth in a congenitally weak area similar to the development of a hernia elsewhere and obviously has a sac except those of traumatic origin due to violent injury, gunshot and stab wounds.

The signs of hernia are varied and inconstant. The first symptom may be manifest soon after birth and be either respiratory or gastrointestinal, or it may develop in later life, as in this child, with symptoms of obstruction which were produced by torsion of the stomach above the pylorus. One must appreciate the various possible signs that could be produced by the stomach filled with air or fluid, the large and small intestines and possibly the spleen, all or part of which may be in the chest cavity, most commonly on the left side. The symptoms may include any combination of the following: cough, dyspnea, cyanosis, decreased respiratory movement on the affected side, bulging of the chest, absence of respiratory murmur and signs of either fluid or pneumothorax. The abdominal signs may be vomiting, nausea, unusually flattened abdomen and signs of obstruction. A dextrocardia should always stimulate a search for diaphragmatic hernias since these are frequently the cause of displacement of the heart to the right side. Following successful repair of the hernia the heart returns to its normal position.

The most important and difficult differentiation to make is that between diaphragmatic hernia and eventration. According to Giffin¹³ the term eventration was first used by Petit in 1790 and applied to the condition of chronic idiopathic unilateral elevation of the diaphragm. He considers it a most unsatisfactory term. Eventration is defined as "protrusion of the bowels through an opening in the abdominal wall." Hernia is defined as "the protrusion of an organ or part of an organ or other structure through the wall of a cavity normally containing it." Giffin feels that the terms might easily be interchanged and perhaps rightly so. Since all true hernias must have a sac and since most congenital diaphragmatic hernias and those acquired of traumatic origin have no sac, it would not only be more descriptive but also anatomically correct were the terms to be reversed.

There has been a marked increase in the cases diagnosed and reported in recent years. This is due chiefly to the advance in roentgenologic diagnosis.

The diagnosis rests chiefly and finally on roentgenologic examination. Some hernias are spontaneously reduced in the upright position. Hence, if there is any doubt as to the diagnosis it is advisable to make the roentgenologic examination in either the horizontal or Trendelenburg position. Once the diagnosis is made, surgical intervention should follow, because the mortality is much higher in complicated cases such as the one above reported. The operative mortality has been greatly reduced in recent years. Hedblom¹⁴ states that among 57 cases reported during the last three years the immediate result was good in 72 per cent. There were eight deaths, a mortality of 14 per cent.

This type of dextrocardia is not generally included in the classification of congenital dextrocardias. Dextrocardia secondary to congenital diaphragmatic eventration or hernia is obviously congenital, but it is caused by pathologic conditions similar or identical in principle to the dextrocardias of acquired origin. Since the term congenital merely means to be born with, I think it is preferable that this type of case be classified as "congenital dextrocardia with acquired characteristics." Paradoxical as it may appear I feel that it is quite descriptive. Jones¹⁵ gives a similar classification for this group. By dextrocardia of acquired origin is meant a heart which has been displaced to the right from the normal left-sided position which it had occupied, by some pathological process.

The following cases illustrate the acquired type.

Case 6 M. M., colored female, aged 10 years (of the tuberculosis research group), was referred for physical examination because of marked disease in the right lung and a dextrocardia. On inquiring whether there were any complaints we were told "just pain in the chest" and "hoarseness."

Family History Father and mother in good health. Five children, none dead, no history of tuberculosis in the family.

Past History Normal birth, no asphyxia or cyanosis, normal development, first tooth at five months, walked at nine months and talked at one year. Had measles and whooping cough. The mother stated that the child had no respiratory trouble.

Physical Examination Malnourished in appearance, enlarged cervical lymph nodes, foul breath, tonsils large, cryptic, almost meet in the midline. Chest is narrow, asymmetrical, right chest is smaller and retracted, marked Harrison's groove, impairment of resonance over whole right chest with fine and large moist râles scattered throughout, particularly the upper half. The breath sounds increased on the right side. There was a hyperresonant note on the left side. The apex beat was on the right side near the nipple line in the fourth interspace about 5 cm. from the mid-sternal line. Four tuberculin tests (Mantoux) with increasing strengths were negative (the strongest dilution being 1-10).

Electrocardiogram 1 Normal sinus rhythm. 2 Normal A-V conduction time. 3 Neither right nor left axis deviation.

Fluoroscopic examination corroborated the roentgenographic (figure 6) findings of dextrocardia and marked right-sided pulmonary disease. There was retraction of the right chest with diminished respiratory movements. Bands of pleuro-pericardial adhesions were distinctly visible which were undoubtedly binding the heart to the right side.

Diagnosis Non-tuberculous fibrosis of the right lung with pleuro-pericardial adhesions causing dextrocardia.

FIG 6 *Case 6* M M, female, colored, aged 10 years (May 1, 1933) Dextrocardia secondary to pulmonary infiltration and pleuro-pericardial adhesions with emphysema of the left side

It was difficult at the time definitely to rule out a pneumothorax. The absence of the retracted visceral pleural line that is seen in pneumothorax, the findings on fluoroscopy, particularly the pleuro-pericardial adhesions, the persistence of the dextrocardia to date since first noted in May 1933 (patient was reexamined in April 1934, and dextrocardia was still present but with somewhat diminished pulmonary infiltration on the right side) and the subsequent course leave little doubt as to the diagnosis. On November 19, 1934, she was admitted to the children's ward in Jamaica Hospital with an extensive bronchopneumonia on the left side and dextrocardia. After the bronchopneumonia had subsided the dextrocardia still persisted. At this time the child was again fluoroscoped, and the pleuro-pericardial adhesions were visible on the right side.

The following case of dextrocardia in an adult was similar to but much

more advanced than the case just reported, and the report of autopsy is available *

Case 7 L. G., male, aged 42 years Admitted Dec 9, 1932, died Dec 28, 1932
Chief complaint Dyspnea and orthopnea

Present Illness Hacking cough, productive, started two weeks ago Had similar attack two and one-half years ago During recent attack feet were swollen The swelling decreased when he stayed in bed

Past History About 12 years ago patient first noticed that he became short of breath and about that time developed a cough, at first dry but later productive

Physical Examination On admission temperature 99.8° F, pulse 96, and respirations 30 The patient is a well nourished adult male, perspiring and coughing persistently, forcefully and productively

Chest Impairment of resonance on right side with increased vocal and tactile fremitus along entire right side anteriorly and posteriorly There are numerous crackling râles at the right base Heart Maximum impulse felt in the third right interspace 8 cm from mid-sternal line First sound moderately loud and short Faint systolic blow and short presystolic murmur

Röntgen-ray diagnosis 1 Dextrocardia 2 Chronic infiltrative process in the right lung with retraction of chest wall and displacement of the trachea 3 Small exudate in right chest 4 Chronic bronchitis and bronchiectasis of left lung

Electrocardiogram Normal rhythm No mirror inversion image in Lead I Left axis deviation of the QRS T₁ and T₂ are diphasic There are premature ventricular beats in Leads II and III

Clinical conclusion Ventricular myocardial disease

Patient became progressively worse with a rising temperature and died Dec 28, 1932

Summary of autopsy findings 1 Non-tuberculous fibrosis of right lung, incident to old interstitial pneumonia with pleuro-pericardial adhesions, compensatory enlargement of left lung with minimal apical fibrosis, diffuse suppurative bronchitis and bronchopneumonia 2 Dextrocardia with cardiac hypertrophy and dilatation 3 Cirrhosis of spleen and kidneys 4 Chronic passive congestion of spleen and kidneys 5 Supernumerary nipple

Cause of death Bronchopneumonia

Diagnosis Dextrocardia secondary to non-tuberculous fibrosis of the right lung and pleuro-pericardial adhesions

Comment I have added this adult case, not only because of its autopsy findings, but also by way of complement to the preceding case of M. M., aged 10 years, also with dextrocardia, pleuro-pericardial adhesions and pulmonary infiltration It pictures to us the probable outcome of the child in the not too distant future In both cases there was considerable compensatory emphysema of the left lung It is difficult to say how much of the cardiac displacement is due to the emphysema It is easily conceivable that it does exert some force If that is so, then there are two distinct forces exerted in the same direction in displacing the heart to produce the above type of dextrocardia, fibrosis of the lung with fibrous bands causing traction, or a pulling force on the heart, and an emphysema pushing the heart to the right

* This case was on the service of Dr. Carl Boettiger, at the Mary Immaculate Hospital, Jamaica, to whom I am indebted for permission to report it

Case 8 G W, male, aged 21 months

Past History Irrelevant

Present Illness Ill for about one week prior to admission to hospital January 22, 1935, at which time he was extremely ill, cyanotic, dyspneic. Temperature 100°. Evidence of consolidation of the left lower lobe. Five days after admission showed evidence of fluid in the left chest. Fluid increased very rapidly with evidence of cardiac displacement to the right. Paracentesis performed and pus was removed from the left chest. Roentgen-ray revealed evidence of a great deal of fluid in the left chest with considerable displacement of the heart and trachea to the right. Child was operated upon immediately for empyema, made a good recovery, and heart returned to its normal position.

Diagnosis Dextrocardia secondary to empyema on the left side

Comment The causes of acquired dextrocardia are many. Any condition which can cause displacement of the heart to the right side can produce a dextrocardia. In its normal position approximately two-thirds of the heart lies to the left. Obviously there may be various degrees of dextrocardia from partial to complete. Among the numerous conditions reported causing dextrocardia are: On the right side—tuberculous fibrosis, non-tuberculous fibrosis, pleuro-pericardial adhesions, atelectasis and carcinoma. (In 16 cases of acquired dextrocardia reported by Hedblom¹¹ three were due to carcinoma of the right lung.) On the left side—diaphragmatic hernia and eventration, tumor or cysts of the lung, fluid in left chest and pneumothorax. Miscellaneous causes include scoliosis, megacolon and mediastinal emphysema. The symptoms naturally are dependent upon the underlying cause.

SUMMARY

Eight cases of dextrocardia are reported, three of which were discovered in a series of 11,253 roentgen-rays of children's chests. These eight cases were as follows:

- 1 A true mirror picture dextrocardia with situs inversus
- 2 Dextrocardia secondary to congenital eventration of the diaphragm
- 3 Acquired dextrocardia secondary to pleuro-pericardial adhesions with non-tuberculous infiltration of the right lung
- 4 and 5 Two additional cases of true congenital mirror picture dextrocardia, one of which was associated with a patent interventricular septum, cyanosis and myocardial disease involving the bundle of His
- 6 Dextrocardia secondary to congenital diaphragmatic hernia
- 7 Dextrocardia secondary to non-tuberculous fibrosis and pleuro-pericardial adhesions in an adult with autopsy findings
- 8 Dextrocardia secondary to empyema on the left side

A modified classification of dextrocardia is proposed

I CONGENITAL

- 1 True mirror picture dextrocardia (A) with situs inversus, (B) isolated congenital dextrocardia without situs inversus
- 2 Dextrocardia due to arrest of development

- 3 Congenital dextrocardia with acquired characteristics, as that secondary to congenital diaphragmatic hernia, eventration or atelectasis

II ACQUIRED

- 1 Dextrocardia developing after birth secondary to acquired conditions

THE LETHAL EFFECTS OF SOLAR RADIATION ON GUINEA PIGS

By MAX PINNER, M D , F A C P , *Oneonta, N Y* , and AARON E MARGULIS, M D , *Tucson, Arizona*

DURING the last 15 years, a few reports have appeared in the literature in which it was stated that mammals, and particularly rodents, died sometimes when exposed to solar radiation for relatively short periods of time. That radiant energy in certain parts of the spectrum may be lethal for photosensitized animals is well known, but it is interesting to note that several authors were surprised when they observed the lethality of solar insolation for nonsensitized animals. The hitherto published work is based on essentially qualitative studies, none satisfied even elementary physical considerations. There are no adequate measurements of the power γ of the radiant energy that is lethal under the conditions of the particular experimental situation, nor are there any measurements of the spectral distribution of the radiant energy incident upon the test animals. Furthermore there are only totally inadequate attempts to determine the potential dependence of the phenomenon upon variations of the spectral composition of the incident energy. The descriptions of the pathological changes in the test animals are incomplete and controversial.

We stumbled on the observation that guinea-pigs were sensitive to radiant energy and that they died regularly within an hour when exposed to the midday sun at Tucson, Arizona (altitude 2,600 feet, latitude $32^{\circ} 15'$ North), even at the time of the winter solstice. Since bibliographical search showed us that this phenomenon was little known, that the observed data were inadequate and that the conclusions drawn from them were often erroneous and misleading, we decided to study this condition. Our decision was encouraged by two considerations: (1) that in the Research Institute of the Desert Sanatorium in Tucson we had at our disposal physical apparatus and meteorological conditions suited for such experimental studies, and (2) the thought that the physiological effects of absorbed radiant energy could be studied to best advantage under conditions in which the observable *status quo* is not maintained, i.e., in which physiological compensation is inadequate, rather than the reverse, for complete compensation often obscures the changes initiated by the stimulus. Therefore, the apparent sensitivity of rodents to powers of radiant energy seemed a fertile object for the study of physiological effects produced by this form of energy.

* Presented at the Detroit meeting of the American College of Physicians, March 6 1936.

From the Laboratories of the Desert Sanatorium and Institute of Research, Tucson, Arizona.

γ The term power is used in this paper in its correct physical sense, meaning "rate of flow of energy, i.e. $\text{Power} = \frac{\text{Energy}}{\text{Time}}$."

The experimental apparatus consisted of a Foucault siderostat, carrying a 12-inch square stellite mirror mounted in a dome connected by a passageway with a windowless room free of drafts. The radiant energy of the sun is reflected by such a siderostat in a constant direction, in this instance into the adjoining room, regardless of the changing altitude and azimuth of the sun. The radiation was passed through a 12-inch fused quartz lens of approximately two meter focal length. The shaved ventral surfaces of the guinea pigs were exposed at right angles to the beam through a slit of constant dimensions (2" by 4"). A thermocouple was mounted in the plane of the animal and was connected with a galvanometer of suitable characteristics. The deflections of the latter in response to radiant energy incident upon the receiving surface of the thermocouple had been calibrated for conversion into absolute energy units. Variation in the power of the incident energy was obtained by translational movement of the animal toward or away from the focal point of the quartz lens. Fractionation of the spectrum was accomplished by the interposition in the beam of solar radiant energy of suitable quartz, glass, and liquid filters whose transmission characteristics had been determined by standard spectrometric methods.

Over 100 animals were exposed to various powers of radiant energy of the following spectral compositions

- (a) 0.30μ – 3.0μ (integrated solar radiant energy at Tucson) (34 animals)
- (b) 0.30μ – 1.4μ (integrated solar radiant energy minus "far infra-red") (11 animals)
- (c) 0.37μ – 3.0μ (integrated solar radiant energy minus "ultra-violet") (14 animals)
- (d) 0.37μ – 1.4μ (integrated solar radiant energy minus "far infra-red" and "ultra-violet") (6 animals)
- (e) 0.34μ – 0.66μ (practically only "visible") (24 animals)
- (f) 0.62μ – 3.0μ (practically only "near" and "far infra-red") (11 animals)
- (g) 0.62μ – 1.4μ (practically only "near infra-red") (14 animals)
- (h) 1.0μ – 15.0μ (practically only "far infra-red") (9 animals)—(Artificial source of radiant energy used in this instance)

In each of the above spectral regions, we determined (with due consideration of such variables as body weight, room and body temperature and skin pigmentation) the minimal powers of radiant energy to which the animals regularly succumbed within one hour, they are approximately of the magnitude of those of unconcentrated solar radiation at Tucson. These figures were then corrected for losses by reflection at the surface of the animal. The detailed data will be published elsewhere. Here we wish to report only that *each of the above arbitrary divisions of the solar spectrum can be lethal for guinea pigs* and to describe the clinical and pathological findings, which were remarkably uniform and which, with the exception of

minor details, appeared to be *invariant under variation in spectral composition of the radiant energy to which the animals were exposed*

Under experimental conditions such that death occurs in about one hour, the respiratory rate usually begins to accelerate within 10 minutes after the onset of the exposure, and often attains rates in excess of 180 per minute within 30 or 40 minutes, then the respiration drops suddenly to less than the normal rate and becomes markedly irregular and grunting. The impression was gained that during the last few minutes of life, there develops a discoordination of the respiratory musculature, in the sense that inspiratory and expiratory muscles contract simultaneously. The animals die usually within 10 or 15 minutes following the drop in their respiratory rate.

The rectal temperatures rise rapidly to 108° F or more, usually within 45 minutes. At the time of death the rectal temperature is, in most animals, above 110° F. When the exposure was interrupted after the animal had reached 108° or 109° F, the temperature dropped to normal within less than an hour, and often subsequently to subnormal figures, but the animal died, as a rule, within the next 12 or 24 hours.

In animals that died during the exposure, that is within one hour, or shortly afterwards, the gross autoptic findings were quite uniform throughout. The exposed portions of the skin showed numerous petechiae, the subcutaneous tissues were edematous and congested. The lungs showed areas of massive congestion irregularly scattered throughout the parenchyma, apparently unrelated to the posture of the animal during the exposure. A few animals had a slight amount of free blood in the pleural cavities. The left heart was maximally contracted, the right heart was maximally dilated, a finding characteristic of peripheral vascular paralysis. The liver was diffusely congested, and the gall-bladder was always distended with clear bile if the animal had died during the exposure, but when death was delayed for 10 minutes or more the gall-bladder was found empty. The spleen was moderately or markedly congested, and all the splanchnic vessels were distended with blood. Loops of the intestines and part of the anterior gastric wall directly beneath the abdominal wall had patchy areas of hemorrhagic discoloration and edema, and in some animals there was evidence of hemorrhagic infarction in these areas. The kidneys and adrenals showed varying degrees of congestion. The brain showed no abnormality.

Histological studies revealed a number of different lesions in the lungs, namely (1) massive capillary hyperemia, (2) capillary intraalveolar hemorrhages, (3) small areas of predominantly interstitial lobular pneumonias whose exudate consisted of histiocytes, polymorphonuclears and red cells, (4) scattered, chiefly subpleural, areas of emphysema, (5) markedly contracted bronchial musculature, (6) desquamation of bronchial epithelium, and (7) edema and lymph stasis in the septa. In the involved areas of the gastrointestinal tract, we found simple hyperemia, particularly in the submucosa, massive edema of the same layer, capillary stasis, hemorrhagic in-

fractions and localized complete necroses. Sections through the exposed portions of the abdominal wall showed small cutaneous extravasations, massive subcutaneous edema and, in cases of delayed death, degenerative changes in the superficial layer of muscle fibers. The other organs showed no pathological changes, with the exception of marked congestion.

DISCUSSION

As was mentioned before, previous reports on the lethal effect of radiant energy on mammals both in regard to its physical foundation and to its pathological results are incomplete. In no instance was there measurement by standard physical methods of the power of the radiant energy incident upon the experimental animal. A few authors recorded and reported the readings of mercury in glass-thermometers, the bulbs of which were exposed to the radiant energy incident upon the test animal. Such readings are not at all an absolute measure of the incident radiant energy, but merely represent the equilibrium temperature attained by the glass bulb of the thermometer in contact with the air surrounding it, which in turn depends upon the fractions of the incident energy that are absorbed by the glass bulb and by the air, which vary with the wave-length as well as with the power of the incident energy. For equal powers of radiant energy, a mercury-in-glass-thermometer gives different readings in different parts of the spectrum in which its absorptivity differs. Since no author recorded in absolute units the powers of the radiant energy to which they exposed their animals, their results cannot be compared. If, as was reported in several instances, the results of experiments with artificial sources of radiant energy did not agree with those with solar insolation, that can only mean that in the one instance the flow of radiant energy did, and in the other did not, exceed that rate for which the test animal under the conditions of the experiment could compensate. For, a logical analysis makes it clear that in any given set of conditions, *there must be some rate of flow of incident energy which no animal can survive indefinitely*. No system which is not in energy equilibrium with its environment can maintain its status quo, i.e., a change of state must occur. Since there are physiological limits to the rate at which a given animal can dissipate energy, the problem resolves itself into the determination of that power of incident radiant energy for which the test animal can compensate by an adequate dissipation of energy. If energy intake is continuously greater than energy output, death must eventually occur.

The surprising thing is that the power of unconcentrated solar radiant energy at many places on the earth's surface is of such an order that the compensatory physiological mechanisms of rodents cannot cope with it, not even for relatively short periods of time.

No author has reported or apparently measured the spectral distribution of the radiant energy to which he subjected his experimental animals, in

tact, several used identical sources, but fixed their attention on one zone of the spectrum while disregarding others present. For instance, some authors used the mercury-vapor-lamp as a source rich in "ultra-violet," while others used the same instrument as a source rich in "visible light"—both neglecting the fact that as much as 40 per cent of the total energy of an average mercury-vapor-lamp may be emitted as radiant in wave-lengths longer than $8,000 \text{ \AA}$ (i.e., "infra-red")

One of the main points of discussion in the literature is the question whether the lethal effect of irradiation is due to the "thermic rays," the "light rays" or the "actinic rays." These terms are both ambiguous and misleading. Ambiguous, because they do not denote well defined spectral regions, but only approximate ones. Misleading, because radiant energy is neither "thermic" nor "luminous" nor "actinic" until it is absorbed; whether a given quality and quantity of radiant energy upon absorption will (a) increase the average kinetic energy of the absorbing molecules (i.e., raise the temperature of the absorbing substance), (b) be perceived as light if it falls on the retina, or (c) disrupt molecules (i.e., initiate a chemical change) is *dependent upon the characteristics of the absorbing medium as well as that of the radiant energy*. The term "light" should be restricted to the sensation resulting from stimulation of the retina. For example, if radiant energy of say $4,500 \text{ \AA}$ wave-length falls upon the retina, a sensation of light is experienced, if it falls upon a photographic plate, a chemical change is initiated, and finally if it is directed upon a layer of platinum black, a rise in temperature will ensue, i.e., appear as heat. It remains to be discovered what the response of the skin is to radiant energy of different wave-lengths, but the fortuitous differentiation of the spectrum dependent upon a specialized end-organ, such as the retina, should not be superimposed on other receptors, such as the skin. If the radiant energy of wave-length $6,000 \text{ \AA}$ stimulates the retina, and $8,500 \text{ \AA}$ does not, it does not follow that these spectral regions will produce dissimilar effects in the skin. Whether they do or do not, remains to be determined, and should not be prejudged by labels such as "heat" and "light." Since it is apparent that there must exist for radiant energy of any wave-length *that is absorbed* in no matter what small percentage, some power of incident energy which the test animal cannot survive indefinitely, the problem is therefore not whether the "light rays" or the "heat rays" or the "actinic rays" can be lethal, but what the minimum lethal power is in the various parts of the spectrum under a given set of experimental conditions. This we have determined and the results will be published elsewhere.

The physiological mechanism by which absorbed radiant energy causes death is still unknown and must, for the present, remain a matter of speculation. All of the authors who observed the lethal effect of radiant energy noted that death was in every instance, accompanied by a hyperthermia often exceeding 110° F . The question therefore arises as to whether death

occurs solely because of the production of a hyperthermia. Our findings can be analyzed to give direction for further study. Although we have confirmed that fever is one of the outstanding manifestations, it is not high enough in all animals to cause death per se. In this connection it might be significant, too, to point out again that under appropriate experimental conditions animals die hours after they have regained their normal temperature. It remains to be determined whether the hyperthermia is due simply to the conversion of radiant energy into heat (i.e., an accumulated energy imbalance) or whether it is due, at least in part to indirect causes, such as the liberation of fever-producing substances in those tissues that absorb the radiant energy, or due to a specific physiological derangement of the temperature regulating mechanism by some action of the absorbed radiant energy.

The morphological findings are suggestive of two sets of action: (1) one that is limited to the regions in which radiant energy is undoubtedly absorbed, such as the exposed skin, the underlying subcutaneous tissue and muscle fibers and, apparently the gastric and intestinal walls adjacent to the abdominal wall, and (2) one that is apparently independent of the localization of the incident energy. The direct action is an intense inflammatory stimulus whose initial effect is a marked increase of the permeability of capillaries, for in the regions of direct action we find edema, blood stasis and its sequences all the way to infarction and necrosis. The medium by which the indirect action is conveyed is unknown. Since the skin is undoubtedly severely injured, since the pathological picture is that of generalized vascular paralysis, with practically universal arteriolar and capillary dilatation, since the lungs show patchy emphysema and contraction of bronchial musculature, it is inviting to ascribe the indirect effects to histamine-like substances that may be liberated in the regions of direct action. This is, as yet, no more than a speculation which is, however, susceptible of experimental confirmation.

The most surprising morphological finding is the occurrence of pneumonic lesions in the lungs, these have not been previously recorded. Although it can never be proved that they did not antecede the exposure, we can state definitely that they were present in the majority of all animals killed by radiant energy and that they were absent in all control animals, including those that were treated in exactly the same way as the test animals, except that they were not irradiated. The conclusion seems, therefore, inescapable that they were caused by the absorbed radiant energy. Since these pneumonic lesions were found in animals whose abdomens only were irradiated, they must probably be ascribed to the indirect effects.

Conclusions applicable to man must be drawn with great caution from these experiments, because man has vastly more efficient compensatory mechanisms than has the guinea-pig. The latter has practically no sweat glands; its normal respiratory rate is relatively high so that increased dissipation

pation of heat by increased respiration is quite limited, furthermore its skin is very thin so that radiant energy penetrates probably relatively deeper

On the other hand it is apparent that the initial tissue alterations caused by radiant energy are essentially the same in all mammals

It is probably significant that pulmonary hemorrhages are a constant finding, this may be looked upon as an experimental confirmation of the empirical opinion that insolation may produce hemoptysis in patients with pulmonary lesions. Some of the other findings in our experimental animals bring to mind two clinical conditions in man, namely the so-called "Sonnenbronchitis" of some German authors and the so-called "summer-pneumoniae". But since these two diseases are not generally accepted as clinical entities, and since their pathological substrata are unknown in the first, and not well established in the second disease, we wish only to mention that our findings may possibly have some bearing on these conditions in man.

These studies present, as far as we know, the first experimental proof that radiation in the spectral region $0.34\mu-0.66\mu$ (i.e., almost coinciding with the region called "visible") can produce profound biological effects in non-sensitized animals. In particular, the lethal effect of radiation on mammals in the few instances that have been previously reported, has been uniformly ascribed either to the "ultra-violet" or the "infra-red" portions of the spectrum.

SUMMARY

That mammals, and particularly rodents, may be killed by radiant energy without previous photosensitization, has been observed by a few workers. This phenomenon has, however, never been studied thoroughly, and no attempts have ever been made to measure adequately the incident radiant energy both as regards the minimal lethal power and its spectral distribution.

In experiments that fulfilled these basic physical requirements, the authors have shown

1 Guinea pigs whose shaved abdomen, or thorax, or both is exposed to a sufficient power of solar radiant energy die within one hour with a characteristic sequence of clinical phenomena.

2 The power of radiant energy required for this lethal effect is of the magnitude of solar radiation existing at an altitude of 2,600 feet and a latitude of $32^{\circ} 15'$ North.

3 The spectral regions for which this lethal effect has been proved are as follows

- (a) $0.30\mu-3.0\mu$ (integrated solar radiant energy at Tucson) (34 animals)
- (b) $0.30\mu-1.4\mu$ (integrated solar radiant energy minus "far infra-red")
(11 animals)
- (c) $0.37\mu-3.0\mu$ (integrated solar radiant energy minus "ultra-violet")
(14 animals)

- (d) 0.37μ – 1.4μ (integrated solar radiant energy minus “far infra-red” and “ultra-violet”) (6 animals)
- (e) 0.34μ – 0.66μ (practically only “visible”) (24 animals)
- (f) 0.62μ – 3.0μ (practically only “near” and “far infra-red”) (11 animals)
- (g) 0.62μ – 1.4μ (practically only “near infra-red”) (14 animals)
- (h) 1.0μ – 15.0μ (practically only “far infra-red”) (9 animals)—(Artificial source of radiant energy used in this instance)

4 The pathological findings in the animals that succumbed to the effects of radiant energy are as follows

Massive congestion of lungs, liver, spleen, splanchnic vessels, of those parts of the gastrointestinal canal and of the subcutaneous tissue that lie directly beneath the exposed skin surface, less marked and less constant congestion of kidneys, adrenals and testes. Maximal contraction of the left heart and maximal dilatation of the right heart.

Histologically, small lobular, mainly interstitial pneumonias are frequently seen, associated with these lesions and with irregularly distributed regions of intense capillary congestion, are intraalveolar hemorrhages, patches of mainly subpleural emphysema, contracted bronchi. The intestinal loops and the anterior wall of the stomach show frequently, in addition to massive congestion, stasis, submucous edema, localized hemorrhagic infarctions and necroses.

OCCURRENCE OF MACROCYTIC ANEMIA IN ASSOCIATION WITH LESIONS OF THE BOWEL *

By HUGH R. BUTT, M.D., and CHARLES H. WATKINS, M.D., F.A.C.P.,
Rochester, Minnesota

It is well known that a variety of conditions are often accompanied by a morphologic blood picture resembling, and often indistinguishable from, the blood picture of pernicious anemia. Conspicuous among these conditions are instances in which the intestinal tract is involved in some disease process. This study was undertaken to determine, if possible, just what lesions of the ileum and cecum are likely to be accompanied by an anemia which resembles pernicious anemia.

The first case in which pernicious anemia probably was secondary to an intestinal disturbance was reported by White, in 1890. At necropsy, ulcerative and cicatricial lesions were found in the colon. Faber (1895), according to Strauss, reported the first case in which a blood picture of pernicious anemia apparently was the result of an anatomic abnormality. Two fibrous strictures of the small intestine were found at necropsy. These strictures were probably secondary to a healed tuberculous process. In 1897, Faber reported another case of pernicious anemia which was associated with intestinal obstruction. Since this time blood pictures which are characteristic of pernicious anemia have been reported in cases in which there were various organic abnormalities of the intestinal tract. Seydelhelm, Lehmann, and Wichels (1924) produced a stenosis in the small intestines of dogs, and in two of the 10 animals the blood picture resembled that of pernicious anemia. These same workers (1927) mention a case in which pernicious anemia developed secondary to a stricture of the small intestine. When the stricture was surgically eradicated the blood picture became normal. Little, Zerfas, and Tiusler (1929) reported the development of the blood picture of pernicious anemia in a case in which there was a stricture of the small intestine. The anemia, however, was not relieved when the bowel was restored to its normal state. In a review of the literature, in 1929, Meulengracht found 22 cases in which pernicious anemia apparently was the result of organic abnormalities of the intestinal tract. In 18 of these cases there was a stricture of the small intestines, in three there was a stricture of the colon, and in one there was a stricture of the cecum. Schlesinger (1933) observed a case in which pernicious anemia occurred secondary to intestinal stenosis. In the stomach, however, he still found the intrinsic factor (Castle). This evidence suggested that the pernicious

* Submitted for publication May 25, 1936.

anemia was caused by faulty absorption in the intestinal tract. Strauss (1934) mentioned a boy, eight years of age, who had pernicious anemia following the development of numerous short circuits between various loops of small intestine. Strauss also reported a case of pernicious anemia in which the patient was a man who was receiving an adequate diet and whose gastric juice contained the intrinsic factor. The patient, however, had pernicious anemia apparently because he was unable to absorb material necessary for formation of blood, because of multiple intestinal anastomoses.

Miller and Rhoads (1935) have produced macrocytic anemia in swine by feeding them a deficient diet. Achlorhydria, diarrhea, and changes in the bone marrow, which were characteristic of pernicious anemia, also occurred. Remissions could be produced by feeding liver extract. Unpublished work in their laboratories suggested that the lack of an intestinal secretion is not the only important factor. After resection of almost the entire ileum of dogs, the blood picture was only that of a mild hypochromic anemia. These investigators said that "apparently some disorder involving both the stomach and intestine is required to produce the desired results."

Ivy, Richter, Meyer, and Greengard (1934) observed that dogs deprived of their stomachs had a hypochromic anemia that responded to administration of iron. Brown (1934) intimated that pernicious anemia is almost invariably associated with lesions of the gastrointestinal tract.

It would seem that a number of conditions which involve the intestinal tract may, therefore, be accompanied by the blood picture of pernicious anemia.

Hartmann and Pilliet first described hypertrophic intestinal tuberculosis in 1891. The studies by Rubin (1930) indicate that gastrointestinal tuberculosis is common among patients who die of chronic pulmonary tuberculosis. Davis (1933) observed that in 22 of 29 cases of intestinal tuberculosis the involvement was at the ileocecal region. Keefer, Huang and Yang (1929) pointed out that in cases of intestinal tuberculosis the degree of hypochromic anemia was greater in cases in which diarrhea was present than it was in cases in which diarrhea did not occur. However, Brown and Sampson (1930) are among the few writers who have stated that intestinal tuberculosis might produce a blood picture suggestive of pernicious anemia. In such cases, they considered the frequently associated stricture of the small bowel as the possible etiologic factor in the production of this blood picture. No anemia, however, was reported by Masson and McIndoe (1929) or by Counsellor (1929) in their cases of hyperplastic tuberculosis of the ileum.

Regional ileitis, as first described by Crohn, Ginzburg, and Oppenheimer (1932), was supposedly confined to the ileum and was usually accompanied by a moderate progressive anemia. More recently, Harris, Bell, and Brun (1933) and Homans and Hass (1933) have observed that the condition might occur at any point in the intestinal tract. Bissell (1934), Binney (1935), and Mixer (1935) did not mention anemia in their reports but Brown, Bargin, and Weber (1934) observed a mild to a moderate secondary

anemia in 50 per cent of 18 cases of regional ileitis. A review of the literature does not reveal any cases of regional ileitis in which there was a macrocytic type of anemia.

It is well recognized that anemia may be associated with diarrheal diseases which cause little or no hemorrhage. This may, in part, be the result of a deficiency associated with the rapid flow of intestinal contents and a resulting want of absorption in the intestine. Cramer (1923) and Goldblatt and Benischek (1927) found that both vitamins A and B were necessary for the development of the healthy mucous membrane of the intestines and for maintaining its resistance to infection. Tilden and Miller (1930) observed marked changes in the colon and clinical signs of human colitis among monkeys which were fed with diets which were deficient in vitamins. Keefer, Yang and Huang (1929-1931) reported several cases in which chronic dysentery was associated with various types of anemia. The anemia varied in its severity and in its morphologic characteristics. Hyperchromic, hypochromic, macrocytic, and microcytic types of anemia were observed. Even the characteristic clinical features of pernicious anemia were present in some of these cases. In some of the cases the anemia responded to the administration of liver, iron, or a high caloric diet, in some cases the anemia improved after the patients recovered from the dysentery. These authors concluded that the syndrome of pernicious anemia can develop without changes in gastric acidity in cases in which patients have received inadequate diets and have had a pathologic process which interfered with normal nutrition.

We might mention the frequent association of the blood picture of pernicious anemia with other conditions which involve the intestinal tract but which are not considered in this study. Birkeland (1932) in his excellent study on "*Bothriocephalus* anemia" considered in detail the relation between *Diphyllobothrium latum* and pernicious anemia. Logan (1921) reported four cases in which there was infestation with *Balantidium coli*. All of these patients had a blood picture of pernicious anemia and, in addition, had subacute combined sclerosis. Reed and Wyckoff (1926), Baumgartner and Smith (1927), and Castle, Rhoads, Lawson and Payne (1935) have pointed out the similarity between the blood picture of sprue and that of pernicious anemia. Other workers have observed the similarity in the microscopic appearance of the intestine in sprue (Castle, Rhoads, Lawson, and Payne, 1935), intestinal infantilism (Bennett, Hunter, and Vaughan, 1932) and various types of chronic diarrhea (Linder and Harris, 1930). Wills (1934) reported a few cases of tropical macrocytic anemia in which the anemia was distinctly different from pernicious anemia and was not necessarily associated with diarrhea, defective gastric secretion, or pregnancy.

An explanation of the production of the macrocytic anemia that frequently is seen in association with lesions of the intestinal tract has been offered by Castle and his coworkers (1929, 1930, 1931). Castle, Town-

send, and Heath (1930) said "Next to a defect of the original formative process within the stomach, the loss of the absorptive power of the intestinal tract either mechanically or by way of bacterial invasion or the destruction in the bowel of the effective principle after formation would be the most obvious ways in which a deficiency of the final effective substance could be brought out. These remarks indicate that a defect of gastric function alone is not necessarily the only way in which, quite in accord with our hypothesis of the nature of the disease, a deficiency of the necessary substance might be produced." This existence of intestinal impermeability to the hematopoietic products of gastric activity appears very plausible from the work of Gansslen (1930). He first demonstrated the increased effectiveness of the active principle of liver when given intramuscularly instead of by mouth. This work was later confirmed by Schilling (1931). It therefore appears that the macrocytic anemia produced in certain lesions of the intestinal tract probably is the result of disturbance in either the formation or the absorption of the final effective principle. It recently has been suggested (Eros and Kunos, 1936) that hematopoietic substances are produced not only in the stomach but also in the entire intestinal tract, in other secretory organs, and in all organs containing an argentaffin cell system.

MATERIAL EXAMINED

This paper is based on a series of 20 cases (table 1) in which anemia was associated with lesions of the ileum and colon. These cases have been studied from the standpoint of type of anemia, and the type of lesion has been verified at operation.

TABLE I
Conditions Found at Operation and Type of Anemia Present

Condition found	Number of cases	Macrocytosis or picture of pernicious anemia, cases	Hypochromic, microcytic anemia, cases	Hypochromic, normocytic anemia, cases
Inflammation of terminal portion of ileum	7	6	1	0
Ulcer of the ileum	4	1	1	2
Carcinoma of cecum	3	1	0	2
Fecal fistulas	2	1	1	0
Tuberculosis of ileum and cecum	2	0	2	0
Carcinoma of ileum	1	1	0	0
Diverticulosis of colon and chronic ulcerative colitis	1	1	0	0
Total	20	11	5	4

In seven cases of proved ileitis of the terminal portion of the ileum there were six instances of macrocytic anemia and in the remaining case the anemia was of the microcytic hypochromic type. Apparently, the macrocytosis was not dependent on the degree of involvement of the ileum because

the extent of involvement of the ileum was as great in the case in which microcytosis occurred as it was in the remaining six cases. Hemorrhage was not a factor as it was not present in any of the cases. The patient who had microcytic hypochromic anemia was a male, which would rule out the possibility that a primary microcytic hypochromic anemia might have been the basis for the microcytosis. One of these cases is of particular interest because a diagnosis of pernicious anemia had been made and the patient had received adequate treatment for pernicious anemia before coming to the clinic. Free hydrochloric acid was present in the gastric contents. Large doses of liver extract administered parenterally for 10 days prior to operation did not produce any change in the degree of anemia. There was no increase in the percentage of reticulated erythrocytes. At operation the patient was found to have an extensive inflammation of the lower portion of the ileum with slight obstruction. Following operation the blood picture gradually improved and within one month the number of corpuscles was normal and the erythrocytes were normal in size. During this period no treatment for the anemia was given. In the cases in which the patients survived the operation, the blood rapidly returned to normal without specific treatment. Three patients died following operation.

In the six cases in which macrocytic anemia was present, the erythrocytes were well filled with hemoglobin and closely simulated those found in cases of pernicious anemia. However, there was but little poikilocytosis as compared with the degree usually seen in pernicious anemia. The leukocyte picture as a rule showed a shift of the neutrophils to the left and in no instance was there a shift to the right with thinning and stranding of the individual lobes of the nucleus as is so characteristically seen in cases of pernicious anemia. It thus will be seen that, in spite of a high color index, detailed study of the morphology of the blood will not show the typical features of pernicious anemia and in all such instances detailed study of the patient for a disease other than pernicious anemia should be instigated. It is possible that an individual might have pernicious anemia associated with ileitis. In such instances one would expect the anemia to persist after operation, and there most probably would be symptoms of pernicious anemia, such as glossitis, symptoms of combined sclerosis, and achlorhydria.

Four patients who had an ulcer of the ileum also had hypochromic anemia. In one of these cases the anemia was of the macrocytic hypochromic type, in two cases it was of the normocytic hypochromic type, and in the remaining case it was of the microcytic hypochromic type. In the case in which there was macrocytosis, the ulcer had produced obstruction, whereas in the other three cases there was no obstruction. The patient who had macrocytic hypochromic anemia occasionally had had tarry stools for two months previous to his registration at the clinic. At operation an ulcer was found $11\frac{1}{2}$ feet (45.7 cm) above the ileocecal valve and obstruction was present. Eight centimeters of ileum were removed. The blood returned to normal following operation and the macrocytosis disappeared.

In the other three cases there was no evidence of obstruction and no macrocytosis was found, the erythrocytes were normal in size in two of these cases and microcytic in one case. In one of the cases in which the size of the erythrocytes was normal the patient had had tarry stools for eight years prior to operation. In the case of microcytic hypochromic anemia there was no history of hemorrhage and at operation an inflammatory ulcer was found in a Meckel's diverticulum. The fact that this patient was a male would rule out the possibility of a primary microcytic anemia. In three of these cases the blood returned to normal postoperatively. One of the patients who had hypochromic normocytic anemia died shortly after operation.

In a case of obstructive carcinoma of the terminal portion of the ileum, vomiting was present and there was a macrocytic hypochromic anemia. A normocytic hypochromic anemia was present in three cases of carcinoma of the cecum, in one of these cases there was slight obstruction. The patient who had macrocytic anemia had no symptoms of pernicious anemia, although gastric analysis revealed an absence of free hydrochloric acid. Following operation the macrocytosis disappeared and the blood gradually returned to normal.

In two cases of fecal fistula one of the patients had hypochromic anemia and the other presented the typical blood picture of pernicious anemia although there was less shift of the neutrophils to the right than there usually is in pernicious anemia. The latter patient also had glossitis, numbness and tingling of the fingers and toes, and achlorhydria. Neurologic examination revealed the presence of subacute combined sclerosis and peripheral neuritis. Following operation, the anemia persisted but responded readily to intramuscular administration of liver extract. This patient undoubtedly had a true pernicious anemia with an associated fecal fistula. This patient died a few weeks after operation. The other patient had a hypochromic anemia of the microcytic type. Operation revealed multiple fistulas which involved about 17 cm. of the ileum. The blood returned to normal within three months after operation.

Two patients who had tuberculosis of the terminal portion of the ileum and of the cecum also had a microcytic hypochromic anemia. There was no history of hemorrhage or obstruction in either case. Gastric analysis revealed an absence of free hydrochloric acid in both cases.

One patient who had diverticulosis of the left half of the colon and chronic ulcerative colitis of the right half of the colon also had a macrocytic anemia with high color index. There was no free hydrochloric acid in the gastric contents. The blood did not respond to adequate treatment for pernicious anemia but the patient recovered spontaneously two years after he left the clinic.

COMMENT

It is apparent that regional ileitis may produce a macrocytic anemia which apparently is independent of the amount of involvement of the ileum.

There was as much bowel diseased in one case of microcytic hypochromic anemia as there was in any of the six cases of macrocytic anemia. Hemorrhage was not a factor in this series of cases. There apparently is some abnormality of absorption and a situation possibly is produced in which there is improper utilization of the effective fraction by the liver, for in this group of cases no change in the blood picture was noted after parenteral administration of liver fractions that are effective in the treatment of pernicious anemia. In the two cases of tuberculous involvement of the ileum there was no macrocytic anemia, which may indicate that in such processes there is no abnormality of formation or absorption of the hematopoietic principle. Any lesion of the bowel that produces obstruction may so interfere with the absorption or utilization of the hematopoietic principle that a macrocytic anemia will result. Only one case of diverticulosis of the colon and chronic ulcerative colitis was studied and in this case there was a macrocytic anemia. There was no history of obstruction. The macrocytosis disappeared spontaneously.

TABLE II
Cases of Hypochromic Anemia

Case	Chief complaint	Condition found	Blood picture previous to operation
1	Diarrhea of several months' duration	Extensive inflammation of lower portion of ileum and slight obstruction	Hypochromic, microcytic anemia*
2	Fecal fistula that followed appendectomy two months previously	Multiple fecal fistulas in ileum	Hypochromic, microcytic anemia
3	Intermittent abdominal cramps over entire abdomen for 10 years	Tuberculosis of terminal two feet of ileum and of cecum, with slight obstruction	Hypochromic, microcytic anemia
4	Intermittent cramps in left upper quadrant of abdomen for two years	Tuberculosis of terminal two feet of ileum and of cecum	Hypochromic, microcytic anemia
5	Intermittent cramping pains across midabdomen for 18 months	Simple solitary ulcer of ileum, 2 cm in diameter	Hypochromic, normocytic anemia*
6	Tarry and bloody stools intermittently for eight years	Inflammatory annular ulcer of ileum, involving 10 cm of ileum	Hypochromic, normocytic anemia
7	Intermittent abdominal cramping pains for three years	Angulated loop of ileum with Meckel's diverticulum which contained an inflammatory ulcer	Hypochromic, microcytic anemia
8	Intermittent cramping pains in left lower quadrant of abdomen for two months	Perforating carcinoma of cecum with involvement of 10 cm of ileum	Hypochromic, normocytic anemia
9	Colicky pains in right lower quadrant of abdomen and diarrhea of six months' duration	Cecal carcinoma (grade 2) with partial obstruction of lower portion of ileum	Hypochromic, normocytic anemia

* Patient died following operation

If macrocytic anemia is attributable only to failure of absorption of the effective hematopoietic principle, the anemia should respond to effective liver fractions administered parenterally, but this did not occur in two cases in which the patients were adequately treated. It would appear that in regional ileitis particularly, the process in some manner produces some change, perhaps in the form of a toxin, which prevents utilization of the hematopoietic principle by the liver. Since in most instances, as has been previously stated,

TABLE III
Cases with Blood Picture of Pernicious Anemia or Macrocytosis

Case	Chief complaint	Condition found	Blood picture previous to operation
1	Intermittent cramping abdominal pains for eight years	Inflammation of terminal portion of ileum and dilated loops of intestine	Macrocytosis
2	Dull, intermittent abdominal cramps for three years	Distal 25 to 30 cm of ileum involved in inflammatory reaction	Macrocytosis*
3	Constipation for 20 years	Regional ileitis	Macrocytosis*
4	Intermittent low cramping abdominal pain for five years	Inflammation of terminal portion of ileum, with some dilatation and obstruction	Macrocytic, hypochromic anemia
5	Numbness and tingling of hands and feet, pain in right lower quadrant of abdomen, diarrhea for three months	Inflammatory lesion involving cecum and 8 cm of ileum	Macrocytic, hypochromic anemia
6	Cramping, intermittent pains in right lower quadrant of abdomen for two years. Condition diagnosed as pernicious anemia and patient treated with liver before admission	Extensive inflammation of lower portion of ileum with slight obstruction	Pernicious anemia
7	Cramping pain in right lower abdominal quadrant with vomiting for two months	Carcinoma of terminal portion of ileum with obstruction	Macrocytosis
8	Recurrent numbness and tingling of the feet and hands for nine years, constant dull aching pain in right upper quadrant of abdomen for one month	Diverticulosis of the left half of colon and chronic ulcerative colitis of the right half of colon	Macrocytosis
9	Anemia and weakness for one year	Carcinoma (grade 2) of cecum	Slight macrocytosis suggestive of pernicious anemia
10	Intermittent abdominal cramps for four years and severe cramping pain in lower part of abdomen for seven months	Subacute ulcer of ileum with partial obstruction	Macrocytosis
11	Numbness and tingling of hands and feet with sore tongue for eight weeks, fecal fistula for 12 years, diarrhea for one year	Multiple fecal fistula of the small intestine	Pernicious anemia*

* Patient died following operation

the blood picture can be distinguished from that seen in pernicious anemia, the finding suggests that factors other than failure of absorption and utilization of the hematopoietic principle may produce a macrocytic type of anemia

Since the macrocytosis and anemia disappeared following operation in this series of cases, it would not seem essential to treat such an anemia with materials effective in the treatment of pernicious anemia. It seems to us, however, that for good therapeutics such preparations should be used and preferably by the parenteral method as this should result in a rapid response of the blood to normal. One should have constantly in mind the possible coexistence of pernicious anemia, and in cases in which the clinical findings support a diagnosis of pernicious anemia, the treatment must be continued after operative procedures.

The most outstanding symptom in this series of cases was cramping abdominal pain (tables 2 and 3). We wish to emphasize that this symptom, particularly in the presence of macrocytic anemia without symptoms of pernicious anemia, strongly suggests a lesion of the ileum.

It also should be emphasized that macrocytic anemia does not always mean pernicious anemia or sprue, but in such cases patients should be studied in detail to eliminate lesions of the small intestine or liver. This is especially true if the patient presents none of the symptoms of pernicious anemia.

SUMMARY

Macrocytic anemia frequently affects individuals who are suffering from regional ileitis. Any intestinal lesion which produces obstruction may produce a macrocytic anemia. Carcinoma of the cecum, tuberculous ileitis, and fecal fistulas did not produce a macrocytic anemia.

Parenteral administration of liver was not effective in the treatment of the anemia associated with regional ileitis. The condition of the blood improved spontaneously following operation. Coexistence of pernicious anemia and lesions of the intestine has been considered.

MEDICO-DENTAL RELATIONS, THE DENTIST'S VIEWPOINT *

By J T O'ROURKE, B S , D D S , F C A D , *Louisville, Kentucky*

THE question of medico-dental relations is one which has been discussed for many years. It was originally prompted by the empirical findings of those early practitioners who had observed either a favorable response to the elimination of certain oral conditions, or the damaging effects of faulty dental technology. The case reports of Benjamin Rush and his contemporaries on the benefits frequently accompanying the elimination of oral infections are well known. The period in which these early practitioners lived did not offer such opportunities for investigation as exist today, yet their frequent reports on medico-dental relations are not without value.

The first school of dentistry was founded (1840) with full recognition of the existence and value of the then known medico-dental relations. The objectives of the school according to one of its founders, Chapin A. Harris, M D,¹ is "to give those who receive its instructions a thorough medico-dental education, so that when they enter upon the active duties of the profession they may be enabled to practice it, not alone as a mere mechanical art, but upon sound scientific principles, as a regular branch of medicine." Dr. Thomas Bond, one of the faculty of the first school, states in the introduction to his *Practical Treatise on Dental Medicine*² that "the purpose of the present work is to present to the reader a digest of information prepared with particular reference to the morbid connections certainly existing between the teeth and the rest of the body."

The handicaps imposed by the continued existence of apprenticeship methods, the rise of commercialism in many dental schools, inhibited the attainment of the health service objectives of the early schools, and dentistry for the most part continued to limit its activities to dental technology. Medicine, busy creating and utilizing new knowledge in its field, also left untouched areas now recognized as having medico-dental relations. It was not until the early part of the twentieth century that the findings of Hunter, Billings and others stimulated interest and further investigation into the possible relations which oral infections may have as etiologic factors in systemic disease. Though early interest and enthusiasm on the subject were accompanied by many misinterpretations which have led to radical and fanatic therapy, that period fortunately is about ended, and an era characterized by conservative, though progressive, attitudes has now begun.

The modern concept of medico-dental relations includes, in so far as

* Presented at the Detroit meeting of the American College of Physicians, March 3 1936

we have been able to determine, several general phases namely, the effects which oral diseases or disorders may have as etiologic factors in systemic disease, in the aggravation of already existing conditions, in the establishment of a negative phase of body defense factors, as the cause of certain reflex disturbances, and finally, the changes in the oral hard and soft tissues due to systemic disease or metabolic disorder. Obviously there is in each phase the same difficulty in establishing absolute proof that exists in connection with the etiology of many diseases.

McNevin and Vaughan,⁴ in a discussion of focal infection, state that (1) "Even if absolute proof of the existence of oral and other foci of infection cannot be submitted, it is nevertheless a reasonable assumption", that (2) "The strong circumstantial evidence advanced, strengthens the assumption", and (3) "The exact nature, however, of the effect which oral foci exert on the body, in each case cannot always be determined". From the viewpoint of the dentist, it is not any spectacular nature or effect of oral foci which should cause them to command attention, but rather the great frequency with which they occur. It is one thing to attach little importance to a single oral lesion, but quite another to disregard the probable effects of many carious teeth, or multiple supporting tissue lesions, in the mouth of one patient. It is the rare individual today who does not harbor either one important or several minor foci. Clinical search for spectacular or potent oral foci often overshadows consideration of the long range effects of those of apparently lesser and more immediate import. If it be true that most diseases are due to a combination of forces, may it not be said that apparently harmless multiple foci constitute a force, which though it may not be the most active, is nevertheless a needless burden to the individual? Perhaps we dwell too heavily on this point, however, it is prompted by the appallingly high incidence of mouth filth, dental caries, and so-called pyorrhea among American people. One has but to examine several thousand adults or children to reach the conclusion that a large number are carrying multiple oral foci which should be eliminated.

Much has been written regarding the routes by which the products of oral sepsis may be transported to other parts. For the most part, emphasis on the spread of infection by the blood and lymph stream has excluded consideration of the probable effects of transfer by swallowing, aspiration, or by continuity of tissue. Because of the location of oral infections and the great frequency with which they occur, should not these avenues for the spread of septic products be rated higher in importance than they now are? Even though the transfer of infection by continuity of tissue, aspiration or swallowing be regarded as devoid of significance in the etiology of respiratory or gastrointestinal diseases, may it not impose aggravating factors which make successful treatment difficult? In view of the widespread lack of mouth hygiene, the high incidence of dental caries and pyorrhea, it is not illogical to assume that effective mouth hygiene offers some protection against certain respiratory or gastrointestinal diseases.

The physician should have knowledge of all of the oral disease or disorders of his patient, therefore, the report of the dentist should be a comprehensive one, going far beyond the now too common, and too limited statement as to the patient's oral condition. These reports, I believe, should include data relative to conditions which may bear causal relations to systemic disease. There are good reasons for the assumption that there should be included information as to the extent of dental caries, pulpless teeth, infections of the periodontal tissues, alveolar abscesses, residual infection, impacted teeth, mouth filth, and marked malocclusion.

Dental caries, the most frequently occurring physical defect among civilized peoples, has for years been regarded as a condition to be treated from a point of tooth conservation. From research findings and clinical observation one is led to conclude that dental caries, especially in youth, may be regarded as an important focus of infection. It has been shown by Noyes, Fish and others that fluids may easily be passed through the tubules of the dentin to the pulp. Hartzell and Henrici⁴ state that, "Our results confirm in a general way the studies of Collins and Lyne. If our observations are correct we must conclude that in approximately one-half of the number of teeth invaded by caries or surrounded by pyorrhea, the pulps are already infected by streptococci." In 1920 these investigators state that subsequent studies give "ample confirmation of the opinion previously arrived at from bacteriological studies that the pulp may be (a) invaded by microorganisms long before it is actually exposed by caries, and (b) may be repeatedly injured by microorganisms long before it actually undergoes necrosis." Thoma⁵ has shown that the *Streptococcus viridans* is the most important factor in pulp infection. He states that in 16 out of 21 cases with closed pulp chambers pure cultures of *Streptococcus viridans* were produced, and concludes that "an infected vital pulp, no matter whether there are marked periapical changes or not, is often a very important focus of infection."

The evidences of favorable response to the treatment of dental caries is too frequent to put to one side as being without significance. The elimination of lymphadenitis, and the increase in alertness and in general well-being have been observed many times in this country and abroad. While there are involved such other factors as the relief of pain and more effective mastication, we believe that treatment which stops the transfer of septic products through the tubules of the dentin to the pulp under biting stress or perhaps without it, is in the main responsible.

The oral focus about which more has been written than any other is the chronic alveolar infection. Presenting as it does a closed focus, there is much to prove that it is a common etiologic factor in diseases of adjacent and remote structures. It would be out of place here to enumerate the list of specific conditions commonly ascribed to these foci. It should be said, however, that it is all too common practice to consider chronic alveolar abscesses as the only oral source of focal infection. There is no sound basis for the apparent exclusion of other foci which may also be present. Neither

are there any grounds for the optimism so frequently encountered in the absence of gross radiographic evidence. Any estimate of the effects of these infections as judged by radiographic evidence is obviously unreliable. It has not yet been shown that pulpless teeth can be successfully treated, and until this proof is at hand, protection of the patient should warrant their removal. Statements that the extraction of such teeth is not always followed by a favorable response are somewhat beyond the point. Dental infections may not have been a cause of the disease under consideration, however, they should be rated as potentially dangerous and therefore eliminated.

As to the condition commonly called pyorrhea, there appears to be much confusion as to the part which it may play in systemic infection. Much of the confusion results from the fact that all too frequently all changes in the supporting tissues of the teeth are included under the term pyorrhea. Atrophic changes, so-called recession, of the alveolar and periodontal tissues are unimportant as etiologic factors in focal infection, however, because these atrophic changes are often accompanied by increased mobility of the teeth, a focus of infection is often assumed to exist and extraction of the teeth is advised. It is the periodontal infection, or the suppurating pyorrhea pocket, which should command the interest of the physician. The tissues involved in this condition, abundantly supplied as they are with lymphatic and capillary blood vessels, offer many avenues for the extension of bacteria and their products. The disease should be regarded as a focus of infection of considerable importance, not only because it affords opportunities for metastasis, but also for the reason that drainage from the suppurating tissues tends to raise the oral bacterial count to a high point. The accompanying increase in mouth bacteria, though usually disregarded, may in chronic suppurating infection of the alveoli and periodontal tissues establish by a spread of infection through aspiration, continuity of tissue, or swallowing, relations to diseases of the gastrointestinal, and upper and lower respiratory tract. Whether or not one accepts mouth bacteria as bearing causal relations to these diseases, it appears that in their treatment at least, the establishment and maintenance of mouth hygiene should be good routine practice.

Yet another common oral source of infection is seen in the residual areas remaining in the soft tissue of alveolar bone following the removal of teeth. They are caused by leaving infected root apices, cysts, foreign bodies, loose particles of alveolar bone, or by the incomplete removal of pathologic tissue. These residual areas are so frequently found in the partially or completely edentulous jaw, that the absence of teeth still leaves ground for suspicion that such areas may exist. It is also good routine practice to suspect the presence of unerupted teeth in the edentulous jaw. The patient is not usually conscious of the presence of residual areas, unless symptoms of acute infection arise, therefore, for practical diagnostic purposes absence of local symptoms does not warrant the assumption that these areas do not exist and bear some relation to diseases of adjacent or remote tissues.

In addition to oral infections and their possible relations to systemic disease, the reflex disturbance frequently established by unerupted and impacted teeth, pulp stones and sclerotic bone are of interest. The removal of these occasional causes of reflex disturbance have so often brought relief, that they should be of considerable import in oral diagnosis.

In considering oral infections in their relation to systemic disease, it is frequently stated that individuals may carry most of them without apparent harm. However, one must conclude that the body defense factors are not inexhaustible, and even though one held that oral infections are devoid of direct causal relations in systemic disease, it would be difficult to justify a premise which held that they did not constitute a needless burden which tended to jeopardize the defensive powers of the individual. In persons who have lost much of their normal defense, the coexistence of chronic oral infections with systemic disease is too frequent to be overlooked.

It is interesting to note the views of Haden,⁶ who states that "In studying patients with systemic disease of focal origin, all possible foci of infection should have careful clinical consideration. Every student of focal infection is impressed with the fact that no subject in medicine must be handled with more mature clinical judgment when one sees the harmful results of the reckless removal of teeth, the frequent ascribing of conditions to focal infection when due to entirely different causes, and careless promises for the relief of systemic lesions by the extraction of teeth. Careful study of the subject must convince one of the importance of dental focal infection in the causation of systemic disease."

Pemberton,⁷ in speaking of the removal of focal infection in arthritis, makes an excellent point when he states that "Much emphasis will be placed here upon the removal of focal infection, but the importance of a medical understanding of the individual as a whole precedes this. Notwithstanding the theoretical propriety of removing infections, any step in this direction may, especially in the later stages, be not only unprofitable but dangerous." This statement is especially applicable to the removal of oral infections. Very frequently when systemic disease demands the removal of these infections, the extraction of a number of teeth at one period is followed by severe reactions and exacerbation of the patient's symptoms. In the terminal diseases, the gradual elimination of oral infections, sometimes over a period of weeks appears to be good practice.

Another side of the question of medico-dental relations includes those points at which the dentist should refer his patient to the physician. In general this is indicated when (a) it is thought that systemic conditions are etiologic factors in the establishment and maintenance of certain oral diseases, disorders or deficiencies, and (b) when oral manifestations of systemic disease, for which the patient is not being treated, are recognized by the dentist. To the end that graduates in dentistry shall be more capable of initiating intelligent action on these two points, American dental education has made important changes in its curriculum and objectives.

As yet the exciting cause of dental caries is unknown, therefore preventive measures are for the most part empirical. There appears, however, to be general recognition of the value of high structural resistance to dental caries, and to the protection afforded by harmonious and adequate development of jaws and teeth. Inasmuch as tooth development begins in intra-uterine life, and as the follicles of both the deciduous and permanent teeth are developed at birth, one may well say that the problem of satisfactory development, and the prevention of dental caries in part at least, up to the eruption of the first tooth, is one for the physician. It is well known that up to this point many things may happen to prevent harmonious development. Over these disturbing factors, the dentist has no control. Therefore, the physician must in the main be responsible for the inauguration of such preventive or therapeutic measures as may be necessary.

It is difficult to agree with those who approach the problem of arresting or preventing dental caries through dietary measures alone. The simple administration of calcium or phosphorus compounds and vitamin bearing substances guarantees little, unless it can be shown that dietary deficiencies actually exist. Medical understanding of the patient as a whole is necessary for the reason that many factors may prohibit assimilation and fixation of inorganic salts. The patient may be suffering from some systemic disease or metabolic disorder or may be eliminating desirable inorganic salts too rapidly. Diagnosis by the physician should be the basis for judgment in the matter of diet as a preventive measure in dental caries. The physician and the dentist, cooperating in arresting or preventing this widespread condition, can accomplish much more than can either one alone.

The frequent need for cooperation of the internist is evident in the prevention and treatment of supporting changes (pyorrhea) when one considers the constitutional factors usually involved. These changes seldom occur before middle age, and are rarely established in a marked way so long as the patient has sufficient resistance to withstand the burdens imposed by such local factors as malocclusion, faulty restorative work, or inadequate mouth hygiene. Obviously certain changes can be accounted for in terms of advancing age, however, both acute and chronic systemic disorders usually leave their mark on the alveolar and periodontal tissues and in addition lower their resistance to infectious and mechanical stresses. These oral manifestations of metabolic disturbances present a much wider field than is ordinarily thought. They include such conditions as diabetes which, in addition to lowering resistance, may be accompanied by changes in the oral mucous membrane, anemias, with their frequent oral symptoms, malnutrition with its accompanying deficiencies, nephritis and many other conditions which obviously need not be considered here. It is sufficient to repeat that such conditions play no small part in disturbing the health of the alveolar and periodontal tissues. Most human dentures are so poorly developed, or become so damaged through caries, that harmonious function of the denture is impossible. Factors of ill health imposed on existing disharmonies often

bring about complete edentulation in early middle life. The search for a single local etiologic factor in supporting tissue changes, or the attempt to prevent or successfully treat these conditions as purely local changes, is for the most part futile. Diagnosis and treatment by the internist in a large number of cases is either a prerequisite to or accompaniment of successful dental service in preventing or treating these conditions.

The illustrations which have been drawn serve only to show examples of areas having medico-dental relations. In the past these areas have been relatively untouched by either medicine or dentistry. Dentistry largely because of certain heritages which it had difficulty in overcoming, centered its efforts for the most part on restorative and replacement procedures. As research and clinical observation caused revival of interest in the relation of oral sepsis to systemic disease, changes in attitude began to take place. The key to the solution of the problem, dental education, was stimulated by an excellent report on dental education by the Carnegie Foundation. Among other things this report held that dentistry "properly a form of health service," expanded as it should be in biological scope and strengthened in its health service aspects, would be devoted, "to detection and provisional diagnosis of dental and oral symptoms that indicate the prevalence or imply the probable existence of ill health elsewhere in the body and to suitable, supplemental, advisory health service including consultation with the patient's physician, based on such observation and diagnosis."

Following a four year curriculum study in which medico-dental relations played an important part, the American Association of Dental Schools adopted among other objectives of dental education, those which call for the education of students in order that they may be (*a*) competent in the maintenance of oral health, and in the treatment of oral diseases, disorders and deficiencies with understanding and appreciation of the relationships between oral and systemic conditions in health and disease, and (*b*) be able to cooperate effectively with persons engaged in allied fields of service. Recommendations relative to a suggested curriculum leading to attainment of these objectives were also adopted by the Association.

There is sound basis for anticipating that research and clinical observations will show even more important and more extensive medico-dental relations than are now thought to exist. Utilization of knowledge in the areas which have so long been neglected depends primarily on education and cooperation. Dental education is taking many forward steps and by 1937 nearly all dental schools will require two years' pre-dental work for admission to improved four year courses. Dental organizations are becoming increasingly more active in the promotion of research in the biological phases of dentistry. In general, trends indicate a healthy forward movement to new goals and to the acceptance of broader responsibilities in the health service field.

In closing, may I express appreciation for the cooperative spirit with which medicine has approached problems involving medico-dental relation-

ships It has been both helpful and encouraging Continued and extended cooperation between the two professions will, I am certain, mean much to the patient, the physician, and the dentist

CASE REPORTS

ACUTE GUMMATOUS MYOCARDITIS SIMULATING ACUTE MYOCARDIAL INFARCTION¹

By EDWARD C. REITENSTEIN, M.D., F.A.C.P., *Syracuse, N. Y.*

CORONARY thrombosis was rarely diagnosed ante mortem prior to 1918. At that time textbooks on medicine contained no reference to the clinical condition. It is a tribute to American medicine that the clinical recognition of cardiac infarction is due to the observations and studies of American physicians.

Osler¹ was familiar with the condition. Dock² was one of the first to describe a case which had been diagnosed ante mortem. However, its significance was not appreciated until Herrick in 1912³ and again in 1918⁴ had described its clinical features and drawn attention to the fact that it could be easily diagnosed and that many cases recovered.

The importance of the subject soon became quite apparent, so that within a comparatively short time it was more frequently recognized and diagnosed, at first, as is usual, in places where teaching was done. The transition in the state of our knowledge of the condition was ably expressed by Christian⁵ in 1925: "Twenty-five years ago, cardiac infarction as a result of coronary thrombosis had been shown to me in the postmortem room but I recall no reference to cardiac infarction or, as it is sometimes termed, coronary thrombosis, as a condition to be recognized during life. My teachers of that day seemed unable to make the diagnosis in the clinic. Today I find that fourth year medical students in my wards at the Peter Bent Brigham Hospital consider it in rendering a diagnosis on a patient assigned to them for history and physical examination, and adopt or eliminate it with a very considerable degree of accuracy. In other words, the students of today diagnose with much accuracy a condition that was hardly known to medical students twenty-five years ago."

The older practicing physicians were naturally slower to appreciate the condition. However, with increasing knowledge, they too have become familiar with it, so that today coronary thrombosis is frequently and usually correctly diagnosed by the practicing physician. Hamman⁶ expresses very well the change which has occurred: "Ten years ago I was often called to see patients with symptoms of collapse following a severe attack of pain in the chest, and under these circumstances had the satisfaction of pointing out how simply the diagnosis of coronary thrombosis could be made. Today the humblest practitioner of medicine is so familiar with the clinical picture and so alive to its recognition that the opinion of the consultant is seldom needed to suggest the diagnosis. Now when almost every sudden pain in the chest of a person past middle life is called coronary occlusion, it seems appropriate to sound a warning. There are other diseases of the heart, lungs, and abdominal organs which so closely

¹ Read at the Detroit meeting of the American College of Physicians, March 6, 1936.
From the Department of Medicine, College of Medicine, Syracuse University.

resemble coronary occlusion that they are often distinguishable from it only with great difficulty and sometimes not until autopsy discloses in detail the real state of affairs."

This coincides with my experience. Paradoxically, the consultant no longer introduces the diagnosis of myocardial infarction, but now either confirms it or diagnoses one of the less common but equally important conditions simulating myocardial infarction.

Naturally, at first mistakes in diagnosis occurred because the clinical condition was not clearly understood. One of the errors was to diagnose an acute surgical condition in the abdomen because of the prominence of the abdominal symptoms, and in several instances exploration of the abdomen was done and no pathology found. Later the correct diagnosis was shown at autopsy. Levine and Tranter⁷ and later others, Hamburger,⁸ Hardt,⁹ Anderson,¹⁰ Coffen and Rush,¹¹ Portis,¹² directed attention to this phase of the problem.

Now the situation is reversed. Failure to recognize myocardial infarction rarely occurs. In fact, it is sometimes erroneously diagnosed in the presence of conditions which resemble it. The error may prove serious or even fatal to the patient, especially if the condition is one which could have been relieved by proper medical or surgical procedures. Within the past few years the literature on this subject has contained reports of various conditions which simulate myocardial infarction. Among these are acute pericarditis,^{6, 20} pulmonary embolism,^{1, 15, 16, 17, 20} acute upper abdominal disease,^{6, 8, 19, 20, 21, 20} interstitial emphysema,⁶ ruptured aorta,^{6, 26, 27} dissecting aneurysm of the aorta,^{22, 23} ruptured aortic,²⁸ spontaneous pneumothorax,²⁹ sudden change in the rhythm of the heart.^{30, 31}

I have seen examples of many of these and I have also seen in consultation and on the wards of the University Hospital instances where coronary thrombosis was diagnosed, and the condition later shown to be acute mediastinitis, severe hemorrhage from a duodenal ulcer, acute acidosis associated with diabetes.

It is the purpose of this communication to draw attention to still another condition which presents a confusing resemblance to coronary thrombosis. A patient was observed on the wards of the University Hospital with the symptoms, physical signs, blood pressure readings, laboratory findings, electrocardiographic evidence and clinical course usually considered characteristic of acute myocardial infarction. This similarity justifies the presentation of the details of the case.

CASE REPORT

A white male truck driver, aged 26 years, was admitted to the University Hospital July 6, 1932, acutely ill, complaining of constriction beneath the lower end of the sternum and the upper abdomen and nausea and vomiting of three days' duration. His family history was unimportant. The patient had been married seven years, his wife and one child five years of age were living. Three years ago his wife had a miscarriage at the third month of pregnancy the cause of which was undetermined. Prior to the past year he was employed as a truck driver for a lumber and trucking company and since that time he had done odd jobs as a laborer. During childhood he had measles, mumps, pertussis and scarlet fever. There was no history of diphtheria, pneumonia or rheumatic fever. Seven years before admission he had had a chancre and a gonorrheal infection, two years later he had a generalized body eruption which had reappeared three months prior to admission. Because of the recurrence of the

rash and a four plus Wassermann reaction, he was given a series of intravenous and intramuscular injections. This therapy was discontinued two weeks before admission because of the appearance of a dry, scaly dermatitis upon the hands and the face. His wife, who had also been receiving treatments for syphilis, was then a patient in the University Hospital dangerously ill with a severe form of dermatitis exfoliativa resulting from arsenical medication.

The present illness began on July 3, 1932, three days before admission, with pain and constriction in the lower chest and upper abdomen, nausea, and vomiting. The symptoms persisted and were associated with a non-productive cough, generalized soreness throughout the body, extreme weakness and exhaustion, and severe pain in the lower lumbar region that was aggravated by motion.

The physical examination showed the patient to be acutely ill, in shock, dyspneic, complaining bitterly of a sense of constriction in his chest. The skin revealed a rash with scaly, psoriasis-like lesions located on the abdomen, the arms, and the legs, and also many macules and papules, particularly prominent on the palms of the hands and the soles of the feet. The tongue was red and dry. The oral hygiene was poor and the teeth were decayed. There was no general adenopathy. The veins of the neck were not prominent. The examination of the lungs failed to reveal abnormal findings. The apex beat of the heart could be neither seen nor felt, no cardiac enlargement could be found, and the heart sounds were of faint intensity. The apex rate was 100 beats per minute with regular rhythm. The radial pulse was very feeble and could scarcely be detected. The blood pressure reading was 106 systolic and 80 diastolic. The superficial and deep reflexes were absent. The edges of the spleen and liver were not palpated. There was no pitting edema of the extremities. The temperature on admission was 98 degrees. The following day the temperature was found to be 102.8°, pulse 100, respiration 20. The blood count was as follows: Hemoglobin 89 per cent, red blood cells 5,200,000, white blood cells 23,300, polymorphonuclears 87 per cent, lymphocytes 13 per cent. The examination of the urine showed two plus albumin with numerous hyalin and granular casts. There was an elevated non-protein nitrogen (66.6 milligrams per cent) and a blood sugar of 129 milligrams per cent. The electrocardiogram showed a high take-off of the T-wave in Lead I, with an abnormal take-off of the T-wave in Lead III, having the pattern usually seen in acute myocardial infarction. At this time the heart sounds were less intense, gallop rhythm was present, and moisture appeared in the lungs posteriorly.

The dermatological service reported: "This patient shows a condition suggesting psoriasis by the color, distribution and grouping of the lesions on the abdomen, chest and legs, however, it may possibly be a papulo-squamous syphilitic or arsenical dermatitis."

During the 14 days that he was in the hospital, he continued to have an elevated temperature (figure 1), an increased pulse rate and a persistent leukocytosis. The sedimentation time of the blood was 1 hour and 12 minutes, the blood non-protein nitrogen level varied from 66.6 milligrams per cent to 198 milligrams per cent. The blood Wassermann on admission was reported as showing partial fixation with both antigens, while the second Wassermann reaction was reported as negative. The Wassermann reaction on the spinal fluid was also negative. Electrocardiograms were made every two days and showed consecutive changes (figure 2). The heart sounds continued to vary in intensity with definite gallop rhythm. The blood pressure gradually dropped to 90 systolic and 60 diastolic, signs of circulatory failure increased, and 14 days after admission he expired.

A partial autopsy was performed at the University Hospital July 20, 1932, by Dr. R. B. Hartsfield of the Department of Pathology. "The examination of the peritoneal cavity was negative with the exception of the enlargement of the mesenteric

Fig 1

FIG 2 A—Electrocardiogram taken four days after onset B, C, D, E—Taken at two day intervals Note successive changes in the R-S-T complexes in Leads I and III

lymph nodes Both pleural cavities contained 100 c.c. of slightly blood tinged fluid The pericardial cavity was without evident lesion The heart was found to be somewhat larger than usual and on the exterior surface showed a few milk patches The aortic valve showed some thickening along the line of closure The area of the aorta attached to the heart was considerably thickened and showed pearly gray elevations The other vessels showed nothing unusual The endocardium was somewhat lighter in color than usual The myocardium was lighter in color than usual and there were areas scattered throughout having a reddish streaked appearance This was notably marked in the left ventricle The coronary arteries showed a moderate amount of yellowish thickening, however, no areas of occlusion and no thrombus were found The external surface of the lungs was reddish in color and scattered over the surface of both lungs there were found slightly elevated reddish areas ranging from 1 cm to 3 cm in diameter On section these areas extended down into the lungs and were fairly well demarcated, considerably reddish in color and firmer than the surrounding tissue The remainder of the lung tissue was crepitant throughout The spleen was without evident lesion The liver margins were somewhat rounded, on section the cut surface was mottled yellowish and brownish in color The kidneys showed nothing unusual on external examination On section one small area on the right and two small areas on the left were found that were gray in color and slightly demarcated with a slightly hemorrhagic edge The remainder of the kidney section was not remarkable The capsules stripped with slight difficulty leaving a smooth surface The aorta showed marked thickening and some calcification of the thoracic portion The area above the celiac axis showed similar thickening Mingled with the yellowish elevations were pearly gray elevations which appeared to be the pre-

FIG 3 Heart muscle Area of necrosis showing giant cells in mononuclear reaction

dominating lesion. There was considerable longitudinal wrinkling of the intima. This was most marked in the arch of the aorta which appeared to be slightly dilated. The anatomical diagnosis was syphilitic aortitis, apparent acute myocarditis, multiple infarction of the kidney, multiple infarction of the lungs. "The microscopic examination of the aorta revealed lesions typical of syphilitic aortitis. Examination of the heart muscle showed giant cells in areas showing mononuclear reaction (figure 3). The examination of the aorta and the heart muscle for spirochetes was negative."

DISCUSSION

The symptoms, physical signs, leukocytosis, elevated temperature, increased sedimentation time, and repeated abnormal electrocardiograms warranted a diagnosis of myocardial infarction due to coronary thrombosis, but in an attempt to associate this condition with syphilis, one encountered certain difficulties. It is generally agreed by most writers that syphilis is rarely the cause of coronary thrombosis. Levine³² stated that 4.5 per cent of his cases of coronary thrombosis were syphilitic and that it would not follow that even in these syphilis had a direct causative influence in the coronary thrombosis. That it was so of the patient, aged 36, who was the youngest of his series, seemed likely.

Syphilis is supposed to affect the myocardium in the following ways: (1) Specific fibrous myocarditis of Warthin, (2) Gummatous myocarditis, (3) Involvement of the coronaries either at the ostium or by producing an endarteritis. In our patient, although it was evident that the myocardium was damaged, syphilitic myocarditis did not seem to be the logical diagnosis because the existence of the specific fibrous form has not been definitely proved and because of the rarity of the gummatous type. Pathological studies by Scott,³³ Clawson and Bell,³⁴ Maitland,³⁵ and Saphir³⁶ would indicate that there is no specific form of myocarditis due to syphilis, notwithstanding the observations made by Warthin.³⁷ The pathologist has been unable to differentiate the fibrous changes found in the myocardium in known syphilis from the fibrous changes found in other conditions including arteriosclerosis. This fact and the failure to find spirochetes in the myocardium have been used as evidence against Warthin's³⁷ concept that a specific form of myocarditis is found in syphilis. MacCallum³⁸ states that it is fairly self evident that syphilitic disease of the myocardium could occur in the form described by Warthin, and that it could heal with the traces indicated by such scars is equally clear, but he has seen very few cases in which active syphilitic myocarditis was suggested and has been unable to feel sure that the scars found in the myocardium were really syphilitic. Warthin's views have been supported in some instances by Boyd,³⁹ Wilson,⁴⁰ Paulin,⁴¹ and Hamman and Rich.⁴² The majority agree, however, that it is a rare condition if it exists at all. It might be well to direct attention to the difficulties which Welch,⁴³ Doehle,⁴⁴ and Heller⁴⁵ encountered when they first described changes in the aorta as characteristic of syphilis. For many years the failure to find spirochetes in the aorta was used as an argument against the specificity of the lesions before these lesions were universally accepted as characteristic of syphilitic invasion of the aorta.

It impresses me as being rather unfortunate that the discussion of syphilis of the myocardium has centered around the question as to whether or not a specific form of myocarditis other than the gummatous type occurs. A care-

ful study of the excellent review by Saphir³⁶ obviously discloses that gummatous changes of the myocardium have been reported in many instances. This author in the beginning of his discussion stated that gummatous changes would not be reviewed. However, in 138 chronological case reports which he had reviewed, there were 66 instances in which reference to gummatous changes was made. Recently Sohval⁴⁶ stated that "the acquired tertiary syphilitic disease of the heart (exclusive of syphilitic aortitis with commissural involvement) is infrequent. If one omits from consideration the controversial diffuse fibrous type, the disease may be said to assume the form of diffuse interstitial gummatous myocarditis or that of localized gummatous myocarditis."

Syphilis may affect the coronary arteries either by involving the ostium of the main branch or by producing an endarteritis of the terminal branches. Pincoffs and Love⁴⁷ have recently emphasized the importance of occlusion of orifices of the coronaries in cardiovascular syphilis. In their small series of syphilitic aortitis 71.4 per cent dying a cardiac death showed this lesion. Love and Warner⁴⁸ in a study of syphilis of the heart, coronary ostia and coronary arteries concluded that the lesion of the coronaries most commonly noted was an obliterative endarteritis of the arterioles and that stenosis of the coronary ostia produces the most marked myocardial lesion. They also believe that the myocardial lesions in syphilitic aortitis can be attributed to defective coronary circulation. It is well to direct attention to the fact that, when the ostium of the coronary artery is entirely occluded by syphilis and infarction results, the infarction in no way differs from that associated with arteriosclerosis.

While syphilis of the myocardium is uncommon, there are clinical reports (Brooks,^{49, 50} Coombs,⁵¹ Carter and Baker,⁵² Blackford and Boland,⁵³ Magill⁵⁴) which suggest that it occurs more frequently than pathological studies indicate. If additional methods of study of the myocardium could be found and if more consideration were given to changes affecting the coronary arteries and to gummatous changes, it is possible that the pathologists and clinicians would be more in accord.

I have reviewed all the cases that I can find of syphilis of the myocardium since 1918, the time when Herrick⁴ directed attention to the clinical picture of myocardial infarction, and have been unable to find any reported cases of syphilis of the myocardium with electrocardiographic and pathological studies and findings that resemble the picture of infarction of the myocardium, with the exception of two instances occurring in the Massachusetts General Hospital. The first patient,⁵⁵ a male of 58 years of age, who had had a long anginal history, suddenly died following severe precordial pain. Coronary sclerosis and cardiac infarction were diagnosed. Autopsy showed "the ostium of the right coronary artery completely blocked by a gummatous process. No thrombosis of the coronaries or large infarction of the myocardium was found, however, numerous small fibrous scars were present in the myocardium, particularly in the interventricular septum. The histology of these suggests a luetic process rather than the ordinary fibrosis following circulatory block."

The second instance,⁵⁶ a male of 26 years of age, had an interesting history of three admissions over an eight months' period, in the first admission for jaundice the diagnosis was catarrhal jaundice, in the second because of severe, non-localizing pain and jaundice, a diagnosis of cirrhosis of the liver was made and in the third because of severe precordial pain the condition was diagnosed

as syphilitic heart disease. Autopsy findings supported this last antemortem diagnosis by revealing syphilitic cardiac lesions including myocarditis.

Langeron⁵⁷ reported an interesting case in which the clinical picture of myocardial infarction was present. However, with the final episode no electrocardiographic studies were reported. Autopsy revealed closure of the ostium of the coronary artery. No evidence of infarction was found.

The age of my patient, the history of syphilis, and later skin manifestations justified the opinion that the myocardial damage was associated with syphilitic lesions involving the orifice of the coronary artery and this was the diagnosis on the second day of admission. However, the course and the duration of the illness made the diagnosis unlikely and consequently the final diagnosis was acute myocardial infarction due to coronary thrombosis.

The case is of interest because at autopsy no occlusion of the coronary arteries was found. However, microscopic studies disclosed definite myocardial damage associated with gummata. Careful search for spirochetes in the heart muscle gave negative results. These findings are significant and important because all the symptoms, signs, laboratory and electrocardiographic evidence considered characteristic of myocardial infarction were present. Of special interest in this case are the electrocardiographic findings relative to the R T and S T changes which were of the type usually considered characteristic of myocardial infarction. The autopsy findings support the clinical and experimental observations,^{58, 59, 60, 61, 62} that the R T and S T changes in the electrocardiogram are associated with disturbance of the myocardium.

SUMMARY

A case of acute gummatous myocarditis simulating myocardial infarction is presented. The history, physical examination, laboratory findings, electrocardiographic evidence and clinical course usually considered characteristic of acute myocardial infarction were present. The age of the patient, the history of syphilis, and the secondary skin manifestations justified the admission diagnosis of myocardial infarction from closure of the ostium of the coronary artery due to syphilis, however, because of the duration of the illness the final antemortem diagnosis was acute myocardial infarction due to coronary thrombosis. The autopsy revealed patent coronary arteries, and active granulomatous myocarditis with multiple caseating foci.⁶³ No spirochetes were discovered in the heart muscle. The patent coronary arteries and the extensive myocardial involvement support the theory of the myocardial origin of the R T and S T changes which were found in the electrocardiogram. It is suggested that gummatous myocarditis probably occurs more commonly than has been realized, and that it has not been recognized because too much attention has been given to the yet not generally accepted specific interstitial myocarditis of Warthin. Gummatous myocarditis is presented as another condition to be differentiated in the diagnosis of myocardial infarction.

CONCLUSION

1 While the diagnosis of coronary thrombosis is usually not difficult, occasionally errors are made.

2 Review of the literature reveals that there are conditions which closely simulate coronary thrombosis.

3 Whenever the clinical picture of myocardial infarction occurs in a young person who has a history or signs of syphilis, the possibility of syphilis affecting the ostium of the coronary arteries or the myocardium should be carefully considered

4 Evidence is presented to support the theory that the R T and S T changes in the electrocardiogram indicate disturbance of the myocardium

A CASE OF PERNICIOUS ANEMIA AND CHRONIC LYMPHATIC LEUKEMIA ¹

By MURRAY L RICH, M D, and LEON SCHIFF, M D, *Cincinnati, Ohio*

THE combined occurrence of leukemia and pernicious anemia in one individual is undoubtedly rare. In 1900, Leube observed a patient with findings suggestive of both conditions, to which he gave the name "leukanamie." Since then a number of such cases have been reported, chiefly in the German literature. Sinek and Kohn ¹ in 1930 reviewed the reported cases and came to the conclusion that most of them were either a true leukemia with a macrocytic type of anemia, or pernicious anemia with a leukemoid (myeloid) white cell picture. They described a case which they had followed for two and a half years, in which they had made a diagnosis of myeloid leukemia superimposed on a pre-existing pernicious anemia. However, their evidence for the diagnosis of pernicious anemia is not conclusive. While their patient presented a macrocytic anemia, glossitis, increase in serum bilirubin and achlorhydria, no reticulocyte response was recorded and there was only a slight gain in the red count following liver therapy. Beiglbock ² reported a case of subleukemic myeloid leukemia

* Read by title before the meeting of the Central Society for Clinical Research, November, 1934.

From the Department of Internal Medicine, University of Cincinnati and the Medical Service of the Cincinnati General Hospital.

with a clinical picture of pernicious anemia, and also reviewed the literature on the subject. The same objection may be raised to the diagnosis of pernicious anemia in his case as in that of Sinek and Kohn.

We wish to report a case recently studied at the Cincinnati General Hospital in which we feel the diagnosis of both chronic lymphatic leukemia and pernicious anemia is fully justified.

CASE REPORT

The patient, a white male, aged 75, was admitted to the Medical Service of the Cincinnati General Hospital on March 15, 1934. He had been in fairly good health until one year before, when he developed an aching pain in his back, shoulders and thighs, which became progressively worse. He had also noticed increasing weakness and dyspnea on exertion, and more recently some edema of the ankles. His appetite had been fairly good and he had been partaking of an adequate diet, particularly as regards meat and green vegetables. He had not lost weight. There had been some tingling and numbness of the extremities. He had noticed some enlargement of the lymph nodes on the right side of his neck for the past 15 years, but had not been conscious of any recent increase in their size. His general health had been good. In 1927 he underwent an appendectomy for chronic appendicitis in another hospital. No blood counts were recorded at that time. The remainder of the history was not significant.

Physical examination revealed an elderly man, with white hair and a sub-icteric tint to the skin and sclerae. There were no manifestations of purpura. Definite pallor was present. The fundi showed moderate vascular sclerosis and old focal chorioretinitis in the right eye. There was some congestion and edema of the nasal mucosa. The teeth were worn and pyorrhea was present. The tonsils were small and atrophic. The tongue was pale, clean and somewhat smooth around the edges, the papillae were not definitely atrophied. The thyroid was not remarkable. A generalized lymphadenopathy was present, with involvement of the cervical, submaxillary, supraclavicular, infraclavicular, axillary, epitrochlear and inguinal nodes. The glands varied in size from that of a pea to a walnut. They were discrete, firm, not tender and freely movable. The lungs were not remarkable except for moderate senile emphysema. There was no cardiac enlargement as determined by percussion or roentgen-ray. A systolic murmur was heard along the left sternal edge. The rhythm was regular, and the sounds were distant. The peripheral vessels were moderately thickened. The blood pressure was 120 mm of mercury systolic and 85 diastolic. The liver extended 8 cm below the right costal margin, it was firm, smooth and presented a sharp edge. The spleen extended 6 cm below the left costal margin and was firm and slightly tender. No other abdominal masses were felt. A midline ventral hernia was present. There was moderate soft pitting edema of the ankles. The deep reflexes were absent. Position sense was intact. Vibratory sense was absent over the lower extremities. Rectal examination was negative.

The results of various laboratory examinations on admission were as follows. There were 1,200,000 red cells and 40 per cent hemoglobin (Sahli). The white count was 85,800 and the differential smear showed 93 per cent lymphocytes of varying ages, 5 per cent monocytes and 2 per cent neutrophils. The red cells showed poikilocytosis and macrocytosis. The mean corpuscular volume was 111, mean corpuscular hemoglobin 39.8 and mean corpuscular hemoglobin concentration 36.1. The platelets were apparently reduced in number. The urine was negative except for a trace of albumin, which later disappeared. A gastric analysis showed no free HCl following the injection of $\frac{1}{2}$ mg. of histamine, and a total acidity of 6. The Kahn test on the blood was negative. The clotting and bleeding times were normal. The icteric index was 9.7 and the serum bilirubin gave an indirect Van den

Bergh reaction There was no retention of bromsulphalein $\frac{1}{2}$ hour after a dose of 2 mg per kilogram of body weight. The serum protein was 5.71 grams. The non-protein nitrogen of the blood was 26 mg per cent.

The clinical picture together with a white cell count of 85,800, of which over 90 per cent were lymphocytes, established the diagnosis of chronic lymphadenosis (chronic lymphatic leukemia). Because of the high color index and the presence of many macrocytes, it was felt that the patient was also suffering from pernicious anemia. This was further borne out by the histamine achlorhydria, the lack of vibratory sensation over the lower extremities and the hematocrit values.

Accordingly, treatment was begun with liver extract intramuscularly. He was given a total of seven injections, each derived from 100 grams of liver, over a period of 9 days. The reticulocytes, which had varied between 1.5 per cent and 2.5 per cent, began to rise 7 days later, and within two days reached a peak of 16.5 per cent (chart 1). They then fell rapidly to the pre-treatment level, which was reached in 18 days. Further treatment consisted in the administration of 30 grams of Ventriculin daily.

CHART 1

The red count rose gradually from 1,700,000 on March 28, to reach a maximum of 3,300,000 on May 24. There was a corresponding increase in the hemoglobin from 50 per cent to 68 per cent during the same interval. During the remainder of this period of treatment, the reticulocytes varied between 15 per cent and 37 per cent. The white count during this period fell gradually from 120,000 to 40,000 and then rose to 110,000. The differential blood picture continued to show a predominance of old and young lymphocytes. After three weeks of treatment, however, there occurred a small increase in the percentage of neutrophils, and later there was a transient rise in eosinophiles, which numbered 7.5 per cent on March 27.

In order to rule out coincidence, it was decided to see if a reticulocyte response could be obtained a second time. Accordingly, all anti-anemic therapy was discontinued for a period of eight weeks, during which time the bone marrow showed little erythropoietic activity. Almost daily reticulocyte counts varied between 0.5 per cent and 1.5 per cent. The red count dropped to 1,800,000 and the hemoglobin to 44 per cent. The white count rose to 230,000 with over 95 per cent lymphocytes. On August 22, treatment with anti-anemic substances was resumed. Extract derived from 300 grams of liver was given intramuscularly during a period of one week, in

addition to 30 grams of Ventriculin daily. A rise in the reticulocytes again occurred, beginning on the third day and reaching a maximum of 14.1 per cent on the seventh day and returning to the pre-treatment level on the seventeenth day (chart 2). The red count and hemoglobin did not increase as much as before, reaching a level of 2,400,000 and 52 per cent respectively after three weeks. The increase was not maintained, and by the end of September the values had fallen to 1,900,000 and 41 per cent respectively. The dosage of Ventriculin was then increased to 60 grams a day, and in October he was given 11 injections of liver extract. This produced a slight prolonged reticulocytosis and later an increased red count and hemoglobin, the red cells reaching 2,800,000 and the hemoglobin 54 per cent on November 7. The white count did not fall during this second course of treatment, but ranged between 160,000 and 330,000.

An attempt was made to demonstrate the presence or absence of the intrinsic substance in the patient's gastric juice by incubating it with material containing the so-called "extrinsic" factor, but sufficient quantities of gastric juice could not be obtained.

The patient was given 60 grams of Ventriculin daily for the remainder of his illness. The red count gradually fell to 1,900,000 and the hemoglobin to 41 per cent. In December and again in January 1935, he received roentgen-ray therapy over the spleen and cervical nodes, which resulted in a marked drop in the number of white cells.

It is to be noted that the first reticulocyte response was slightly delayed, and submaximal, considering the large amount of potent material given, and that the red count and hemoglobin never reached normal levels. We believe that this may be explained by the fact that the bone marrow was so infiltrated with leukemic tissue as to obviate a normal response. Nevertheless, the red cell count and hemoglobin were increased to the level usually seen in leukemia in an advanced stage.

The patient remained in the hospital until his death one year later. During his stay almost daily studies were made of his blood. Some of these are recorded in table 1. His general condition remained about the same, except for signs of myocardial weakness, until late in February 1935, when he developed a purulent otitis media. Soon after this he contracted pneumonia, which proved fatal on March 6, 1935. Autopsy was performed four hours after death by Dr. James Mack.

The significant findings at necropsy were as follows. There was a generalized lymphadenopathy involving the cervical, infraclavicular, epitrochlear, axillary, inguinal, femoral, mediastinal and abdominal nodes. The glands were soft and yellow in color, and frequently as large as walnuts. There was some myocardial degeneration and fibrosis. The liver weighed 2580 grams, and presented numerous very small nodules on its surface. On section there was a large amount of yellow mottling. The spleen was likewise enlarged, weighing 625 grams. It was soft, with a tense capsule and a smooth uniformly pale red pulp. Microscopically, the lymph nodes were filled with a solid mass of small lymphocytes which completely destroyed the internal structures. There was also evidence of leukemic infiltration of the viscera. The spinal cord showed degenerative changes which were most marked in the posterior and lateral columns. Sections of the bone marrow showed lymphoid infiltration replacing to a great extent the myeloid elements. The erythropoietic centers presented a small number of megaloblasts, as well as normoblasts. Macrocytes were present in every field. The prostate, although grossly not remarkable, gave microscopic evidence of a chronic interstitial prostatitis and an early adenocarcinoma. Lobar pneumonia was present in the left lower lobe and confluent lobular pneumonia in the left upper and right lower lobes.

We believe that the diagnosis of chronic lymphatic leukemia in the case reported cannot be questioned. The enlarged spleen, enlarged lymph glands, per-

sistently high white count with predominance of lymphocytes and the anatomic changes are all typical of this disease. The diagnosis of pernicious anemia is also warranted in view of (1) the macrocytic anemia which responded on two occasions with a rise in reticulocytes and an increase in the red count and hemoglobin after the use of "specific" anti-anemic therapy, (2) achylia gastrica, (3) loss of vibratory sense and (4) degeneration of the posterior and lateral columns of the spinal cord.

No attempt is made to correlate the etiology of these two conditions by the study of this case. In all likelihood, the existence of the two diseases in the same individual was a coincidence.

LIPEMIA ACCOMPANIED BY ATHEROMATOUS AND OCCLUSIVE VASCULAR DISEASE. REPORT OF A CASE AND PARTIAL REVIEW OF THE LITERATURE *

By HAROLD C OCHSNER, M D, F A C P,† and H MILTON CONNER, M D, F A C P, *Rochester, Minnesota*

ACCORDING to Rowland and to Pick, the disorders of lipid metabolism may be classified as essential or primary, and symptomatic or secondary. Among the primary disturbances Rowland considered essential xanthomatosis, with involvement of skin, mucous membranes, tendon sheaths, or viscera, Niemann-Pick disease, Schuller-Christian disease, and Gaucher's disease. As Rowland said, there are cases that defy classification.

The group under present consideration is that which Pick described as the residual group, Rowland as essential xanthomatosis. There is in this group no characteristic age, sex, or racial distribution. The clinical manifestations are extremely varied. There are a number of cutaneous types, varying from the small xanthelasma palpebrarum to general eruptive forms. The mucous membranes may be involved, as in the cases of Finney, Montgomery, and New. They reported from The Mayo Clinic two cases of xanthoma multiplex involving the larynx and trachea, associated with diabetes insipidus. Small subcutaneous xanthomas may occur, and rarely, larger xanthomas may occur as tumors on tendon sheaths and aponeuroses. Visceral involvement of varying extent and location may also occur. In some cases vascular involvement may be the chief manifestation.

These various manifestations may be observed separately or in various com-

binations The characteristic histologic feature of this group of cases is the presence in the involved regions of large, clear, foamy cells containing lipids, in which cholesterol and its esters usually predominate The lipids in the blood may be normal or elevated, and if elevated there is practically always hypercholesterolemia Robertson and Warlen reported a case in which the diagnosis depended on biopsy of a lymph node, the deposits of lipid occurred principally if not entirely in the lymph nodes, and the lipids in the blood were not increased

Investigations have revealed a large number and wide variety of conditions in which a disturbance of the lipids is found as a symptomatic or secondary manifestation Even excitement may produce temporary hypercholesterolemia, Lyons found this to be abolished in cats by sympathectomy

Prolonged obstruction of the biliary tract produces an increase in the level of cholesterol in the blood Gardner and Gainsborough reported this to be true in a case of obstructive jaundice, in a case of stone in the common duct, and in a case of carcinoma of the pancreas and gall-bladder with biliary obstruction Hypercholesterolemia was observed in a case of obstructive jaundice reported by Brain and Byrom, and in cases of subacute yellow atrophy and subchronic atrophy of the liver reported by Adler and Lemmel Similar changes occur in most stages of catarrhal jaundice

An increase of cholesterol and cholesterol esters in the blood often is found in renal disease, notably nephrosis, in two such cases Lichtenstein and Epstein found exceedingly high levels for cholesterol In cases of acute nephritis, Maxwell found the increase in cholesterol to be proportional to the amount of edema, he observed high values for cholesterol in cases of chronic nephritis with or without edema Ashe and Bruger found high values for cholesterol in cases of chronic glomerulonephritis, in some of which the value for urea in the blood was normal, in others elevated Hurxthal, and also Myers, found an increase in the cholesterol in the blood of patients with extensive arteriosclerosis Westphal found that 71.2 per cent of eight patients with hypertension had high values for blood cholesterol, and this was true even in early life

High values for blood cholesterol may also be observed in cases of diabetes mellitus Oppenheimer and Fishberg observed that "The old blood-letters were well aware that under certain conditions, notably severe diabetes mellitus, the blood may contain an excess of fat so great that, on being left to stand, a thick creamy layer separates to the top" Jaffe, Morris, and Schonfeld have reported a case of lipemia retinalis in a diabetic with marked hyperlipemia Lepard reported a case of diabetes with well-marked hyperglycemia and hyperlipemia, cutaneous xanthomas, and lipemia retinalis Curtis, Sheldon, and Eckstein observed that, to have a severe lipemia, the diabetes must be severe, and that the lipemia disappears under control Collins has said that high values for blood fats, and Rabinowitch that high values for blood cholesterol, indicate an unfavorable prognosis in cases of diabetes

Hurxthal stated that, in myxedema, the percentage of increase of cholesterol in the blood is so much greater than the percentage of decrease in the rate of metabolism that the value for cholesterol stands out as an indicator of thyroid deficiency Mason, Hunt, and Hurxthal reported the observation of a series of cases with high values for cholesterol in the blood

Kumpf found that prolonged bleeding leads to persistent lipemia in rabbits Muller found that, regardless of the severity of the anemia, the initiation of a

remission in cases of pernicious anemia is characterized by a sudden increase in blood cholesterol, which during relapse was below normal

Sternberg found increased values for cholesterol in the blood of patients with manic depressive insanity, and Huxthal concluded that hypercholesterolemia is more frequent among patients with mental disease than among those with general disease. McQuarrie, Husted, and Bloor concluded regarding epileptics that "a relative increase of plasma lecithin favors the occurrence of seizures, while a relative increase in cholesterol tends to prevent them." In a study of 100 epileptic and 32 nonepileptic children, McQuarrie, Bloor, Husted, and Patterson found no significant difference in the range of values for plasma cholesterol or in its variability in the two groups. Rosen, Krasnow, and Notkin found that the average values for the cholesterol and lecithin content of the blood in epilepsy were normal.

Rosen and Krasnow observed that, in general, the cholesterol content of whole blood tends to be high in dermatoses. In pregnancy, according to McEachern and Gilmour, cholesterol is increased, particularly in the last trimester. Diets rich in fat, such as the ketogenic diet, lead to an increase in the level of lipids in the blood. Bruger and Poindexter found normal lipid levels in obese individuals without complicating diseases. Prolonged starvation is said by McEachern and Gilmour to lead to an increase of cholesterol in the blood.

An abundant literature confirms the fact that the feeding of diets rich in cholesterol is followed in animals by the formation of atherosclerotic lesions in various vessels. Ignastovskii, in 1908, observed atheromas in the aortas of rabbits after feeding them milk and egg yolks, and this observation was confirmed in 1909 by Starokadomsky and Ssobolew, who found similar changes in the innominate carotid, and subclavian arteries. Anitschkow and Chalutow concluded that cholesterol was the substance responsible for these changes, and in 1913 they produced, by the feeding of pure cholesterol to experimental animals, an aortic sclerosis similar to that observed in man.

Anitschkow, in 1924, found that local vascular changes may be produced in the absence of large increases of lipids if the vessel be traumatized. Whether, as Harris and Lipkin have said, these observations are applicable to man is another question. Leary has observed that man is the only animal that ingests eggs and milk during a lifetime, and man is the only animal that dies in early life from coronary sclerosis and acquires atherosclerosis almost universally in advanced years.

There are a number of reported instances of atheromatous or xanthomatous infiltration of the cardiovascular system in a variety of conditions associated with elevated levels of lipids in the blood. Fagge in 1873, reported the occurrence of xanthomatous infiltration of the left auricle, aorta, and pulmonary, innominate, and carotid arteries of a patient who had long suffered from obstructive jaundice and had numerous cutaneous xanthomas. In the same year Maxon reported the observation of atherosclerosis in a patient with hepatic cirrhosis and cutaneous "xanthelasma." A girl of 11 years, who had cutaneous xanthomas, was examined by Lehzen and Knauss who in 1889 reported that they found yellow raised patches on the mitral valve, producing incompetence, similar changes were observed in the aorta and pulmonary, coronary, and left carotid arteries. Pollosean, in 1890, and Low, in 1910, observed precordial murmurs

in patients who had xanthomas on the skin, but necropsy was not performed in either instance

In 1925 Oppenheimer and Fishbein observed atherosclerotic areas containing large "foamy" cells in the cardiovascular system of a patient who had had papular xanthomatosis and who had died in diabetic coma, similar changes were found in two cases reported by Lutz in 1914. Knox in 1919 observed in a case of Gaucher's disease rows of swollen granular cells, similar to those in the spleen, surrounding the musculature of some of the small arterial twigs. Siegmund in 1921 noted in a case of Gaucher's disease that the endothelium of vessels in the skin, heart, and kidneys contained large lipid cells. Benda in 1924 described the occurrence of xanthomatosis of the pulmonary veins in a case of nephrosis with marked lipidemia. Velhagen in 1914 reported a case of hemorrhagic glaucoma in which there were large clear cells between the endothelium and internal elastic membrane of the central artery of the retina.

CASE REPORT (ABRIDGED)

The patient in the present case a married woman, aged 55 years, came to the Clinic May 7, 1934, complaining principally of weakness, exhaustion, spots before her eyes, and of headache. Her father had died of apoplexy, but the family history was otherwise negative. One of her children was living and well, one had petit and grand mal. The patient had been rather high-strung, had worried greatly, and had had morning headaches for at least 10 years. She had had insomnia and hot flashes for four or five years, but, until 1932, had considered herself in good health.

In August 1932, the patient had not felt well. Some cardiac weakness and a systolic blood pressure of 200 mm. of mercury were found. She had kept moderately quiet. In November 1932, she had suffered much fatigue and pounding in the head and had stayed in bed much of the time during the next four months. The metabolic rate had been normal. In bed, the blood pressure had fallen to 148 mm. of mercury. In June 1933, vertigo suddenly had developed, necessitating rest in bed, this had lasted until fall. In December 1933, the patient suddenly had become blind in the left eye for 15 minutes, and later had had scotomas of various kinds before both eyes. In February 1934, a similar attack had occurred, and she had seen vari-colored lights for two days, at times there had been hemi-vision. Later she had had a feeling as if someone were sitting on her chest, this had been accompanied by discomfort in, and slight disuse of, the left hand. There had been moderate dyspnea on exertion. The history otherwise was not significant.

At the time of examination the patient was found to have a mild elevation of systolic and diastolic blood pressure. On deep inspiration the liver edge was felt hard and sharp one inch (2.5 cm.) below the umbilicus in the mammary line. There was sclerosis, grade 1+, of the retinal arteries, of the hypertensive type, exaggerated disk rings, and mild choroidal degeneration in the region of the maculae. There was no evidence of lipemia in the retinal vessels. Three specimens of urine showed no significant abnormality. Serologic test of the blood for syphilis was negative. Roentgenograms of the head and of both humeri were negative, and those of the lumbar portion of the spine, pelvis, and upper ends of the femurs revealed hypertrophic changes in the lower thoracic and upper lumbar portions of the spinal column but otherwise no structural changes in bone. A roentgenogram of the thorax revealed only slight cardiac enlargement. The value for cholesterol was 667 mg. per 100 cc. of plasma, total fatty acids being 1971 mg., and total lipids 2638 mg. The basal metabolic rate was +8 per cent. Electrocardiograms were normal save for diphasic T-waves in derivations I and II and iso-electric T-waves in derivation III.

Tests of liver function by the Rowntree-Rosenthal method showed the presence of dye in the serum at the end of one hour, it was impossible to determine the degree of retention of dye owing to the high grade lipemia. Total values for lipids in the urine were 22 mg per 100 c c, in a total of 1115 c c of urine constituting a 24 hour specimen. Neurologic examination strongly suggested some cerebral or retinal vascular spasm with residual scotomas, but the neurologic findings were extremely few.

A diagnosis was made of moderate hypertension, arteriosclerosis of the central nervous system and coronary arteries, general arteriosclerosis, moderate enlargement of the liver, cardiac hypertrophy, and lipemia of unknown origin. Because of the unexplained lipemia, together with the absence of significant changes in bony structures, the suggestion of essential xanthomatosis was made and a diet low in fat was recommended.

The patient was permitted to return to her home, where, at our suggestion, a test of sugar tolerance was made, a diabetic type of glucose tolerance curve was obtained. She was given a rather high carbohydrate diet with limitation of fats. Insulin was administered for a time but its use was discontinued because of untoward effects.

The patient returned to the clinic August 2, 1934, she had lost 19 pounds (8.6 kg) and had gradually become weaker. There was weakness but not paralysis of her entire left side, which at times had felt numb, it had tingled and prickled. Sometimes it had been difficult to articulate. The patient gave evidence of loss of weight, but she did not appear acutely ill. There was mild hypertension and the peripheral vessels were sclerotic, grade 2. The heart was slightly enlarged, the liver was palpable on deep inspiration, three fingers' breadth below the costal margin. Gross examination of the eyes gave essentially negative results. The neurologist thought that, on the basis of the complaints referable to the central nervous system, the symptoms were probably on an arteriosclerotic basis.

One week after admission the patient complained of feeling dizzy and of weakness of the left side of her body. Shortly thereafter complete motor paralysis of the left side developed, including the external ocular muscles, together with great difficulty in swallowing and speaking. Spinal puncture revealed nothing abnormal. The most likely diagnosis seemed to be cerebral and pontine thrombosis, although brain tumor or hemorrhage could not be excluded. Because the lesion might be a xanthoma, four roentgen treatments of the brain were given on four successive days. For a short time the patient was given 50 gm of fat per day, but later fat consumed varied from 6 to 50 gm each day. The total daily caloric intake varied from 875 to 1890 during the period of hospitalization. There was gradual improvement of the patient's eyes, speech, and limbs.

Roentgenograms of the head, spinal column, and pelvis revealed no significant changes. Tests of liver function did not reveal retention of dye. There were 30 mg of urea and 81 mg of glucose per 100 c c of blood. Glucose tolerance was normal. All values for plasma lipids are indicated in table 1. Twenty-five days after this admission the glucose tolerance again was found normal.

The patient returned October 2, 1934. After leaving the hospital in August she had improved rapidly for two weeks, after two weeks the improvement had been more gradual. About 10 days before this admission she had had "trembling" in the abdomen, which had been generalized and intermittent, and about the same time she had noticed increased nervous tension, which had persisted. There had been occasional aching in the left arm, and once, a severe pain in it. In the last week she had had a sensation of pressure over the left part of her chest, which had not been accompanied by pain or cardiac palpitation. Her left hand was hypersensitive to heat, the fingers were still somewhat stiff and "felt full." There had been edema of the left hand since the onset of hemiplegia. She had gained 15 pounds (6.8 kg) in the month prior to this admission.

On examination, there was moderate pallor of the skin and mucous membranes, the pupils reacted to light. The heart was slightly enlarged to the left, the tones were good and murmurs were absent. There was peripheral sclerosis, grade 2, and a mild hypertension. The liver edge was palpable three fingers' breadth below the costal margin in the midclavicular line. The spleen was not palpable. There were no abdominal masses and no enlargement of the lymph nodes. There was abortive nystagmus on looking to the left, and slight left facial weakness. Deep reflexes were hyperactive on the left side. There was a positive Hoffman sign in the left hand, but a negative Babinski reflex. Abdominal reflexes were not elicited except in the left lower quadrant, which was hyperactive, grade 2.

The eyes were essentially the same as on the previous visit except for improvement in the strength of the muscles. Four specimens of urine were essentially negative. The values for hemoglobin and the erythrocyte and leukocyte counts were normal, values for lipids in the blood are given in table 1, those for blood urea and sugar were within normal limits. The electrocardiogram was normal save for diphasic T-waves in derivation I. The increase in blood fats despite the low fat diet could not be entirely explained, but it was thought best to continue the diet with the low fat content. For five nights in succession the patient had attacks of severe precordial pain, radiating to the left arm. She of course had not exercised and thought that the pain was not related to excitement. She did state that the pain came on after eating. Physical examination of the heart revealed no abnormality, but, because of the history and the diphasic character of the T-wave in derivation I in the electrocardiogram, it was thought that the attacks were probably anginal in origin. About this time it was thought advisable to lower the caloric content of the diet to 550 each day, the intake of vitamins and minerals was supplemented by giving brewer's yeast (Harris), proprietary tablets of vitamins A and D (Adex), and calcium phosphate.

Although an initial rise in cholesterol occurred on the fourth day, there was a rapid diminution in the fatty acids and total lipids (table 1). There was, however, little subjective improvement in the patient's condition and she continued to have

TABLE I
Lipid Values during Observation, Milligrams per 100 c c

	1934

Grams per day										
Diet while in hospital	8-2		8-12				10-5			10-22
Carbohydrate	300		275				57			261
Protein	60		55				49			100
Fat	50		25				10			21

* On this date, lecithin 371 mg per 100 c c, and cholesterol esters 231 mg per 100 c c of blood

some pain in her left shoulder and arm. October 16, there was an increased weakness of the left arm and leg, with a subjective sensation of numbness. There was definite impairment of speech and deglutition. A rather marked, vertical nystagmus developed, horizontal nystagmus was still present on rotation to either side, and the strength of the right external rectus muscle was still impaired. There was no change in the ocular fields or fundi. October 19 the patient's condition was sufficiently improved to permit further roentgen therapy, and each of four segmental regions of the head was irradiated, one each day. Since the patient still had difficulty with mastication and deglutition and was weaker, it was deemed advisable, on October 22, to increase the caloric intake to 1633, the fat was still markedly limited, to 21 gm daily. The carbohydrate allowance was 261 gm, the protein, 100 gm. Amino-acetic acid was given, one level teaspoonful four times daily.

In the next two days there was an appreciable improvement in the patient's condition, she felt much stronger and was able to sit up in bed for the first time in a week. On October 24 she felt particularly well, until about 6 p.m., when suddenly she had a severe and persistent pain in her left shoulder. This was controlled with some difficulty by opiates. After two hours the patient became unconscious, there was a gradual decline and she died.

Postmortem examination revealed extensive atheromatous changes in the arteries but no organic changes suggestive of any of the named lipid dyscrasias. The heart weighed 342 gm, and there was an increase in fat, grade 1+. At the base of the left ventricle, anteriorly and laterally and extending to the posterior surface, a region supplied by the circumflex branch of the left coronary artery, there was an area of softening, grade 3, of the myocardium. The circumflex branch of the left coronary artery was completely occluded by a thrombus (figure 1). Atherosclerosis, grade 3 to 4, of the coronary arteries was found, and there was atherosclerosis, grade 2, of the thoracic aorta.

FIG 1 Thrombus near origin of circumflex branch of left coronary artery, the atheromatous infiltration is easily seen

The liver extended 1 cm below the costal margin in the midclavicular line and weighed 1983 gm, the cut surface revealed an increase of fat, grade 2, and fat could be seen on the cutting knife. The gall-bladder contained four stones. The spleen weighed 200 gm and was slightly softened, the pancreas weighed 80 gm and revealed

fat replacement, grade 1 The splenic artery was very tortuous and gave evidence of atherosclerotic changes, grade 3 +, on cross section it appeared to be almost completely occluded There was atherosclerosis of the abdominal aorta, grade 3 to 4, with extensive atheromatous abscesses (figure 2)

FIG 2 Aorta, showing extensive atheromatous degeneration and formation of "abscesses"

The vessels of the brain showed extensive atherosclerotic changes, the basilar artery being completely occluded by sclerosis and thrombosis There was slight generalized atrophy of the brain, an infarct measuring 2 by 1 cm on the superior surface of the right lobe of the cerebellum, an infarct measuring 3 by 2 cm in the

posterior apex of the occipital pole of each cerebral hemisphere, an infarct 7 mm in diameter in the right superior olive, and a few small infarcts measuring up to 5 mm in diameter in the right side of the pons

Microscopic examination of the infarcted region of the heart revealed many islands of old and recent infarction, with dense connective tissue replacement in the old and pale-staining tissue and many leukocytes in the newly infarcted area. No intercellular or intracellular fat was seen in the heart except in the infarcted area. In the coronary arteries there was an eccentric intimal thickening, consisting of lipid material and cholesterol crystals. These changes varied in extent from small plaques to complete occlusion of the arteries, there was thrombosis in the region of the atheromatous abscess. In the left descending coronary artery there was complete occlusion and canalization (figure 3)

FIG 3 Left descending coronary artery, showing thrombosis, the lipid infiltration of the entire wall of this vessel is visualized—black staining areas—(low power)

The section of the spleen contained small infarcts. There were scanty lipid deposits in an occasional reticulo-endothelial cell, but no foam cells could be found. In the liver there was moderate congestion and some central atrophy. A fine, fat dust was scattered diffusely within the cells, here, too, no deposits of lipid could be demonstrated that were characteristic of any described lipid dyscrasia. The suprarenal glands showed a rather extensive deposit of lipid, the intracellular lipid being present as droplets. There were lipid-containing cells arranged in radial fasciculi, extending from the capsule through the reticular layer. The alternate bands revealed a fine intracellular fat dusting. The changes were not, however, as pronounced as those sometimes seen in presumably normal glands. The kidneys were essentially normal, although occasional fine lipid droplets could be seen in the collecting tubules and in the intima of the arterioles. The splenic artery revealed extensive atheromatous changes, with complete occlusion in some places. The lymph nodes revealed no abnormality and there were no significant changes in the bone marrow.

COMMENT

There was nothing about the condition of this patient to suggest Gaucher's disease. Schuller-Christian, Niemann-Pick, and Tay-Sach disease were readily excluded on the basis of the patient's age. We felt that the case probably would be best classified as one of essential xanthomatosis and we treated the patient accordingly. No condition other than moderate hypertension and arteriosclerosis was present in which disturbed lipid metabolism has been reported to occur as a secondary manifestation. We do not believe that the degree of hypertension observed in this case, particularly in the absence of significant renal changes, can be considered to be the factor responsible for the disturbed metabolism of lipid. Although one glucose tolerance test was characteristic of diabetes, we feel that the observation of normal levels of blood sugar, the absence of glycosuria, and a normal glucose tolerance response on two occasions exclude the diagnosis of true diabetes mellitus. It would, therefore, seem that this is best classified as a case of so-called "essential" xanthomatosis, with localization primarily in the vascular system. Despite the extremely advanced vascular changes, there were no significant lipid deposits in any other part of the body.

It is interesting in this connection to note the experimental evidence of production of atherosclerotic changes as a result of diets high in cholesterol. So far as we were able to determine, our patient had always adhered to a well-rounded dietary, the elevation in lipid would seem to have been on the basis of an anomaly of lipid metabolism. It seems most reasonable to postulate this as the primary and the atherosclerosis as the secondary manifestation, however, the possibility must be considered that the atheromatous changes in the arteries were primary and the lipemia due to rupture of atheromatous "abscesses."

EDITORIAL

HEAT CRAMPS

IN recent years a considerable literature has sprung up in connection with the clinical condition which in the past has been called by various authors firemen's cramps, stokers' cramps, miners' cramps, cane cutters' cramps or mill cramps, and which is now usually designated by the more general name of heat cramps. This literature has been analyzed by Talbott¹ in a general review in which he includes also a presentation of his own studies in this field.

Heat cramps are a severe form of muscular cramps, occurring chiefly in the extremities, during or following heavy labor, at a high working temperature and in the hot season of the year. They are infrequently seen by the average physician but are well known to the industrial surgeons in the steel mills and in certain mines, as well as to ships' surgeons in the tropics.

These cramps are described as involuntary spasmodic contractions coming on either in isolated groups of muscles in the extremities, as for example in the flexors of the fingers, or affecting more widely the large muscles of the legs, of the arms, of the back or the abdominal wall. Even the facial musculature may be involved. The smooth muscles probably do not participate in the process.

In severe cases the cramps recur every few minutes, the interval lengthening as the attack wears off. The duration of the individual cramp is from one to three minutes and during this time the contracted muscles are stony hard or board-like. The pain is very severe in the stage of paroxysmal contraction but disappears in the interval. The duration of an attack of heat cramps may be from a few hours to several days.

As opposed to heat stroke and heat prostration, heat cramps present rather mild constitutional symptoms. There may be slight headache or vertigo. The temperature is within a normal range. The blood pressure shows no significant change. The pulse and respiratory rate are moderately increased. The severity of the pain in the severe cases may, however, seriously exhaust the patient. Death from uncomplicated heat cramps may occur.

Talbott has made an interesting study of the etiologic factors involved in the production of heat cramps. Foremost among these is the concurrence of a high working temperature and a high atmospheric temperature. In other words, it is in the season or in the geographic location where the worker is exposed to continuous high temperature that heat cramps are most frequent. In the steel mills of the Youngstown district more than 90 per cent of the hospitalized cases are admitted between April and October of each year. The temperature at which heat cramps occur is generally over

* TALBOTT, J. R. Heat cramps, *Medicine*, 1935, xiv, 323-376

100° F Working temperatures in various industries are often extraordinarily high 112° to 135° F in sugar refineries (Coplin), 125° F in the stoke-hole of a warship (Phelps), 150° F in a pullman diner kitchen (Clendening) Even higher temperatures are encountered by certain workers in the steel industry

Contrary to the general impression, the relative humidity of the working atmosphere was not found to be an important factor in the production of heat cramps

Talbott does not discuss in detail the relationship of the character of the muscular work to the incidence of heat cramps It is apparent from its industrial distribution that it is far more common among those doing heavy physical labor There is some evidence also that the cramps are most apt to affect the muscles which have been most actively employed The observation of cramps in pullman cooks indicates, however, that heavy muscular exertion is not an absolute essential It is certainly, nevertheless, a more vital factor in the production of heat cramps than it is in the development of either heat stroke or heat prostration

Defective general hygiene, ill health, inadequate assimilation of food, acute alcoholism and a recent attack of cramps were all found, from an analysis of the series of cases observed by Talbott in the Youngstown area, to be predisposing factors

An important observation which has been made by a number of students of this condition is that the incidence of heat cramps is greatest during the first few days of a hot wave and that there is a decreasing susceptibility as the hot weather continues This plainly suggests the presence of a process of adaptation of the body to continued environmental heat From certain data available it seems probable that the mechanism of this adaptation may involve the amount and the composition of the sweat secreted The observations of Moss* suggest that acclimatization to heat may involve a doubling of the sweat output, while those of Dill† indicate that adaptation includes the secretion of sweat containing a much reduced percentage of chlorides The results of these studies are at present more suggestive than conclusive

It is a point of definite value that the incidence of heat prostration is said to be greatest after the heat wave has continued for some time, since this difference from the time of highest incidence of heat cramps is strongly in favor of a fundamental difference in the pathogenesis of the two conditions Further statistical data to soundly found this distinction would be desirable

Talbott has made careful metabolic studies of 32 cases of heat cramps from the mills of the Youngstown area Very marked changes in concentration of many of the constituents of the blood and urine were found,

* Moss, K N Some effects of high air temperatures and muscular exertion upon colliers, *Proc Roy Soc London, Series B*, 1923-24, xcv, 181

† DILL D B, JONES, B F, EDWARDS, H T, and OBERG, S A Salt economy in extreme dry heat, *Jr Biol Chem*, 1933, c, 755

and as a result of these observations our knowledge of the condition has been notably advanced

The findings in the arterial blood indicated a marked anhydremia. Serum protein was greatly increased on admission—in one instance to 10.6 grams per cent. The increase was found due to the globulin fraction. The serum protein fell toward normal levels during the first days in the hospital but this decrease was not strictly parallel to the improvement in the clinical condition. The concentration of the hemoglobin, as measured by the oxygen capacity, was increased in correspondence to the serum protein increase. The rise in number of red cells paralleled closely the increase in hemoglobin. The anhydremia did not consist only of serum water loss since there was also a loss of 1 to 5 per cent from the red cells. The extent of the concentration of serum protein and hemoglobin was comparable to that found in severe cholera. Blood volume determinations were not made, and data on the specific gravity of the blood are not given.

It is interesting that in spite of these evidences of severe dehydration the amount of urine voided on the day of admission to the hospital was surprisingly large, varying between 400 and 800 c c.

The concentration of electrolytes in the serum of patients with cramps was found altered even in the mild cases. The serum chloride and the serum sodium were consistently diminished. The concentration of serum chlorides on admission was only twice found above 100 m eq and in one case it was 79.8 m eq. The minimum serum sodium concentration was 121.0 m eq and the maximum was 140.0 m eq. The urine in most instances showed a relative absence of sodium and chloride and in severe cases this persisted for several days. During the first few days in hospital balance studies showed a marked retention of sodium, chloride and water with a resultant gain in weight which averaged 4.4 pounds. These findings confirmed and greatly extended earlier observations by Edsall, Raschewskaja and others.

Serum sodium was the only inorganic base whose concentration was decreased in patients suffering from cramps. The concentration of potassium in the serum was normal or increased 1 to 3 m eq, and there was likewise in many patients a distinct increase in calcium concentration. A maximum of 14.3 mg per 100 c c of calcium was observed in two patients. On theoretical grounds the increase of calcium was considered greater than could be accounted for by the calcium binding power of the increased protein.

The variations in the arterial pH's covered a wide range but in most patients the reading was below 7.40, the apparent acidosis being explainable through loss of base. The pH of the urine on admission was usually about 5.0, a degree of acidity greater than was accounted for by the titratable acid found.

There was also noted an unexplained increase in the serum of inorganic

phosphates The non-protein nitrogen was elevated 10 to 25 mg per 100 c c above normal levels Blood sugars were within the normal range

An observation of great interest and possibly of importance was that in 14 of the 32 patients on admission the degree of oxygen saturation of the arterial blood was below 94 per cent and in one patient it was found to be 84.6 per cent

Talbott's analysis of these data has led him to feel that the decrease of serum sodium and serum chloride bears the most constant and significant relationship to the occurrence and severity of the cramps He feels that in each working subject a critical level exists for sodium and chloride, below which muscular cramps occur The loss of serum sodium and chloride is presumably through excessive sweating

The hypothesis is greatly strengthened by the striking therapeutic effects of the administration of sodium chloride as normal salt solution intravenously In severe cases 600 to 1,000 c c of the saline solution were administered, and in all instances the cramps were relieved before the infusion was terminated and could not be brought back thereafter by artificial means In less severe cases the ingestion hourly of a 1 gram salt tablet was effective In the prevention of cramps the value of an increased salt intake has been claimed by a number of observers It has been dispensed to workers in the form of salt tablets but recent opinion favors its introduction into the drinking water to produce a 0.1 per cent concentration Such a solution is without perceptible saline taste

The argument in favor of a specific relationship of lowered serum sodium and chloride to heat cramps would be further strengthened if data from the control series of heat prostration cases had been furnished showing the absence of any similar changes in the serum of these patients

These studies mark a definite advance in our knowledge of this interesting condition It is apparent that the entire mechanism of heat cramps is not yet clear and that many of the actual findings are unexplained, but definite data concerning one fundamental feature of this mechanism have been obtained In how far this knowledge will yield insight into the nature of other varieties of muscle cramps future research will show

REVIEWS

The Practitioner's Library of Medicine and Surgery Supervising Editor, GEORGE BLUMER, M A (Yale), M D, F A C P, David P Smith Clinical Professor of Medicine, Yale University School of Medicine, Consulting Physician to the New Haven Hospital *Volume X Dermatology and Syphilology* Associate Editor C GUY LANE, M D, Instructor in Dermatology and Syphilology, Harvard Medical School lxviii + 1043 pages, 286 illustrations D Appleton-Century Company, Inc, New York 1936 Price, \$10 00 a volume

The tenth volume, Dermatology and Syphilology of The Practitioner's Library of Medicine and Surgery, is a very well planned addition to this series, the preceding volumes of which have been noticed from time to time in the ANNALS This book profits by the advantage derived from having a limited number of contributors, for the monographic treatment of a relatively large field promotes balance and thoroughness Thus we find, among the larger divisions of the volume, General Considerations, by C Guy Lane, constituting a chapter of 99 pages, covering all of the fundamental considerations of histology, physiology, basic lesions, diagnostic methods and general therapy The second chapter dealing with Infections of the Skin, by Frederick D Weidman, requires 200 pages and is admirably done in the concise, illuminating style of which he is a master Again, the chapter on Syphilis, by J E Moore, is 189 pages in length Thus this volume is in fact a group of treatises upon major divisions of dermatology and syphilology by experts in those particular fields

As with other volumes of this series the technical book-making is excellent, and the errors over which reviewers are prone to gloat, extremely few Perfection has, of course, not been attained For instance, Figure 8 on page 843 appears in the list of figures as a chancre of the lip, although the legend accompanying the figure states that a chancre is precisely what the lesion depicted is *not* Seldom have large volumes, such as the members of this series, appeared with as few typographical errors as these have shown

In general, this volume is fully in harmony with the modern trend which relates Dermatology intimately to the practice of Internal Medicine Skin diseases are no longer to be considered as isolated external phenomena, known by purely descriptive terms, but rather as the superficial manifestations of disease states affecting the entire body economy The needs of the general practitioner have been kept in mind, the growing importance of occupational diseases of the skin recognized, and a thoroughly practical discussion of syphilis provided The liberal use of illustrations and the very complete index add to the value of this book as a reference work in the recognition and treatment of the skin conditions which so often come to the attention of the general practitioner

Lactobacillus Acidophilus and Its Therapeutic Application By LEO F RETTGER, MAURICE N LEVY, LOUIS WEINSTEIN and JAMES E WEISS 203 pages, 14 X 21 cm Yale University Press, New Haven, Conn 1935 Price, \$2 50

This volume represents an interesting study of a phase of therapeutics not commonly used by the average physician The authors establish the bacteriological properties of the acidophilus group of organisms and draw attention to the inaccurate nomenclature employed by certain investigators This is particularly true concerning the oral and dental types of lactobacilli which have been confused with *B acidophilus*

The authors stress the fact that acidophilus milk is not a cure-all However, it is useful in instances in which the complaint is directly referable to the gastro-

intestinal tract and especially in cases of simple chronic constipation as well as in many other types of constipation. They believe that other laxatives interfere with the effectiveness of the acidophilus treatment and therefore should be omitted. However, the importance of the oral administration of dextrin and lactose in prolonging the activity of an acidophilus implantation is stressed.

A routine plan of administering *B. acidophilus* in the form of milk is outlined. Even under such conditions implantations were obtained only in certain groups of cases and then often only after several courses of treatment. Of the patients who responded favorably a large percentage became so-called "implanters." Satisfactory results were obtained in many cases of "mucous colitis" or "irritable colon" and in a number of cases of diarrhea associated with ulcerative colitis.

Although these investigations seem promising one has the feeling as one reads the book that inasmuch as the acidophilus group of organisms are short-lived and require constant feeding in order to maintain the acidophilus implantation it is doubtful whether one can hope to obtain a continuous therapeutic effect even in those cases in which implantation has apparently taken place for a period of weeks. Moreover, the authors have observed that continual replenishment of the acidophilus strain by ingestion of acidophilus milk is necessary in the great majority of patients.

S M

The Extra-Ocular Muscles. By LUTHER C. PETER, M.D. 351 pages, 15.5 × 24 cm. Lea and Febiger, Philadelphia. 1936. Price, \$4.50.

This second edition of Dr. Peter's book contains 351 pages with 136 engravings and five colored plates. It is divided into six parts as follows: Part I, Anatomy and Physiology; Part II, Heterophoria; Part III, Heterotropia or Concomitant Squint; Part IV, Paralytic Squint; Part V, Surgical Technique; and Part VI, Nystagmus or Talantropia.

In Part I the anatomical illustrations and descriptions are largely from Whitnall's "Anatomy of the Human Orbit" and are most excellent. That portion which deals with the physiology of the muscles is clearly written and illustrated. Parts II and III devoted to the non-paralytic phorias and tropias are sufficiently clear so that not only the specialist but the internist as well will be able to classify these defects. Part IV which deals with the diplopias and paralytic squints is very clear and explicit. By referring to plates 4 and 5 one should theoretically at least be able to diagnose any type of muscle palsy. Unfortunately, however, most cases are so complicated that even the authorities are often unable to determine just what muscle or group of muscles is involved. In Part V the author describes the surgery of the ocular muscles and outlines the technic of those operations which have been most successful in his hands. In many instances the methods are original while in others they are modifications of previously described operations.

The reviewer regrets that the author did not include the surgery of ptosis as well since this is due to abnormalities of the levator palpebrarum which he describes in the anatomical section.

The publishers as well as the author should be commended for this second edition which brings the subject up to date and thereby fills a want not only for the internist but more especially for the ophthalmologist.

C A C

Treatment in General Practice (Articles republished from the British Medical Journal) 260 pages, 15 × 22 cm. Paul B. Hoeber, Inc., New York. 1936. Price, \$3.50.

The book consists of a number of short articles of variable value on the treatment of certain diseases of the respiratory and cardiovascular systems as well as of certain specific fevers. The editorial policy has been to insist on clarity "to the

point of dogmatism" and there is no doubt but what this objective has been attained. In the section on diseases of the respiratory tract there are many points in symptomatic therapy which physicians in this country will find interesting and valuable, but in general there is little which has not long been included in general practice. A few recommendations are made which are astonishing. "When the patient (with pneumonia) is seen within the first three days a vaccine or a serum should be given. A vaccine has the great advantage that it can be carried in the bag and is immediately available." Under the treatment of asthma by desensitization it is said that "it is better to employ a solution of the four common irritants as one or more of them will be specific for the case, while the others will have a non-specific effect." For technic and dosage the reader is referred to the manufacturer of this solution.

The section on the treatment of certain contagious diseases well repays careful reading though in the article on septicemia the attitude of the writer seems decidedly uncritical.

There is also a great deal of value to certain of the articles on treatment of cardiovascular diseases. In summary, however, the chief interest of the book to the American readers will lie in the opportunity it affords to compare the routine of practice in this country with that in England.

Prescription Writing and Formulary The Art of Prescribing By CHARLES SOLOMON, M D, Assistant Clinical Professor of Medicine, Long Island College of Medicine, with a foreword by Lewellys F Barker, M D. 351 pages, 16 X 23.5 cm. J P Lippincott Co, Philadelphia. 1935.

In the writing of this book, Dr Solomon proposed to bring before the reader the use of drugs in the treatment of disease providing a sound and scientific basis for prescription writing. The book is divided into three parts. Part I is of an introductory nature containing the history of prescription writing from ancient through medieval and modern times. Also there are many practical suggestions to the young physician, such as the prescribing of official remedies rather than proprietary medicines of a more expensive nature. Interesting comments are made on the relationship of the physician and the pharmacist and also on the character and relative usefulness of drugs which are carried in the doctor's handbag. In this section also the absorption and excretion of drugs are discussed in addition to the various avenues of administration. Part II deals with such practical subjects involved in prescription writing as the preparations of solutions, metrology, the use of English and Latin in prescriptions, incompatibilities, construction of the prescription, posology and suggestions for prescription writing. Part III is somewhat separate from the other part of the volume and deals with a number of prescriptions and formulas used in the treatment of the various diseases of the systems of the body. Thus, under drugs having local action, the demulcents and emollients are set forth in typical prescriptions. Under drugs acting on the gastrointestinal tract, the stomachics, antacids and cholagogues are mentioned. In addition there is included a group of biological products illustrating the use of the various serums, vaccines, and antitoxins.

On the whole this volume by Dr Solomon is well written and excellently organized and will serve a very timely need if it reaches the hands of the young practicing physician. Although essentially a book of practical therapeutics its pharmacological foundations are sound. Dr Solomon adheres to the modern principle of simplicity in prescribing and in practically all of the formulas and typical prescriptions included in the book a marked departure from the typical polypharmaceutical prescriptions is noted.

On the whole the author fulfills his purpose in writing this volume and in the reviewer's mind it deserves careful consideration among those physicians who still believe that drugs are an important part of the physician's armamentarium.

COLLEGE NEWS NOTES

GIFTS TO THE COLLEGE LIBRARY

Acknowledgment is made of the following gifts received recently for the Library of the American College of Physicians from the authors

- Dr John Favill (Fellow), Chicago, Ill—1 book, "The Relationship of Eye Muscles to Semicircular Canal Currents in Rotationally Induced Nystagmus",
Dr Samuel Weiss (Fellow), New York, N Y—1 book, "Diseases of the Liver, Gall Bladder, Ducts and Pancreas", 1 bound set, "Clinical Lectures on Gastroenterology," and four reprints,
Dr C Frank Brown (Fellow), Dallas, Tex—2 reprints,
Dr David N Kremer (Fellow), Philadelphia, Pa—2 reprints,
Major James Stevens Simmons (Fellow), M C, U S Army—1 reprint,
Dr William C Cooke (Associate), San Diego, Calif—2 reprints,
Dr Hyman I Goldstein (Associate), Camden, N J—1 reprint
-

PUERTO RICO MEETING OF MEMBERS OF THE COLLEGE

The first formal meeting of the members of the American College of Physicians residing in Puerto Rico was held May 26, 1936, with Dr Ramon Suarez, Governor, presiding

Dr Juan Pons, Dr Harry P Colmore, Dr Antonio Ortiz, Dr O Costa Mandry, R R Rodriguez Molina, Dr Guillermo S Marques and Dr Munoz McCormick were in attendance

Dr Suarez, as Governor, was appointed to act as president of the local chapter, and Dr O Costa Mandry was appointed secretary. It was decided to hold a meeting with a medical program once every two months. The next meeting will be held at the University Hospital, and will consist of clinical conferences and the presentation of cases

Dr W McKim Marriott (Fellow), for several years Dean and Professor of Pediatrics at Washington University School of Medicine, St Louis, has been appointed Dean and Professor of Research Medicine at the University of California Medical School, San Francisco

Major James Stevens Simmons (Fellow) of the Army Medical Research Board, Ancon, C Z, was elected president of the Medical Association of the Isthmian Canal Zone, at a meeting of this organization on June 16, 1936

Dr Ellen C Potter (Fellow), Director of Medicine, Department of Institutions and Agencies of the State of New Jersey, was the recipient of the honorary degree of Doctor of Laws at the commencement of Rutgers University on June 6

Dr Bernard Langdon Wyatt (Fellow), Tucson, Ariz, was unanimously voted the James M Stacey Award for 1936 by the Faculty Council of the College of Medi-

cine, University of Cincinnati, on June 6 The Stacey Award consists of a medal and an honorarium of \$100 00, and is given for significant contribution in the field of focal infection

Dr Samuel E Munson (Fellow), Springfield, Ill, presented a paper on "The Clinical Aspects of Amebiasis" before the annual meeting of the Illinois State Medical Society at Springfield, in connection with a symposium on "Amebiasis," presenting all the phases of the Chicago epidemic of 1933

Dr Hugh B Campbell (Fellow), Norwich, Conn, has been elected vice-president of the Connecticut State Medical Society for the coming year

Major Raymond O Dart (Fellow) of the Army Medical Museum, Washington, addressed the Washington Ophthalmological Society recently on "Ocular Tumors"

Friends and students of Dr Anton J Carlson (Fellow), professor and chairman of the department of physiology, University of Chicago, presented to the University a bust of Dr Carlson, the unveiling ceremonies taking place June 1 Dr Carlson was born in Sweden He came to America in 1891 and studied at Leland Stanford University in California After two years of teaching and research at Stanford University and the Carnegie Institution, he became assistant professor of physiology on the staff of the University of Chicago, and in 1914 was advanced to a full professorship

Life membership in the State Society of Iowa Medical Women was conferred upon Dr Jeannette Dean Throckmorton (Fellow), recently

Dr John A Foley (Associate), heretofore associate professor of medicine, Boston University School of Medicine, has been named clinical professor of medicine in that institution

Dr Lawrason Brown (Fellow), Saranac Lake, N Y, was awarded the honorary degree of Doctor of Science at the annual commencement of the Medical College of Virginia, Richmond, on June 2

A testimonial dinner was recently tendered Dr Charles W Burr (Fellow), Philadelphia, by his friends on the occasion of the fiftieth anniversary of his graduation in medicine and his election to the presidency of the Medical Alumni Society of the University of Pennsylvania Dr Daniel J McCarthy (Fellow) was toastmaster

Dr James H Means (Fellow and president-elect) will be one of the lecturers on the program of the twentieth annual course of medical lectures and clinics presented by the University of Washington during the week of July 20

Dr John G FitzGerald (Fellow), Toronto, has resigned as dean of the Faculty of Medicine of the University of Toronto, in order to make a survey of methods of teaching preventive medicine sponsored by the Rockefeller Foundation. Dr FitzGerald, with Dr Charles Edward Smith of Stanford University School of Medicine assisting, will visit medical schools throughout the United States, Canada, the British Isles and European countries. After the completion of the survey, Dr FitzGerald will return to Toronto as director of the school of hygiene and of the Connaught Laboratories of the University there.

Dr Joseph M Hayman, Jr (Fellow), Cleveland, has been elected secretary of the American Society for Clinical Investigation.

Dr Chester M Jones (Fellow), Boston, and Dr Ernest H Gaither (Fellow), Baltimore, have been elected president and vice-president, respectively, of the American Gastro-Enterological Association.

Dr Henry C Sweany (Fellow), Chicago, will represent the United States in respect to the discussion of the biologic subject, "Radiological Aspects of the Pulmonary Hilum and Their Interpretation," at the tenth conference of the International Union against Tuberculosis, in Lisbon, Portugal, September 7 to 10.

Dr Fred H Kruse (Fellow) and Dr Harry C Shepardson (Fellow) have been made clinical professor of medicine and associate clinical professor of medicine, respectively, on the faculty of the University of California Medical School, San Francisco.

Dr Theodore G Klumpp (Associate), assistant clinical professor of medicine, Yale University School of Medicine, has been given a leave of absence for the academic year 1936 to 1937 to make a study of glandular and antianemic preparations with the Food and Drug Administration of the U S Department of Agriculture, Washington.

Dr Daniel L Finucane (Associate) has been appointed associate professor of clinical medicine at Georgetown University School of Medicine, Washington, D C.

Dr Coursen B Conklin (Fellow) has been reelected secretary of the Medical Society of the District of Columbia.

Under the presidency of Dr Louis H Fligman (Fellow), Helena, Mont, the Medical Association of Montana held its fifty-eighth annual meeting at Billings, Mont, July 8 to 9. Dr Ernest D Hitchcock (Fellow), Great Falls, and Dr Allen R Foss (Fellow), Missoula, delivered papers on "Highlights in Routine Gastric Examinations" and "Manifestations of Allergy in General Practice," respectively.

The Catawba Valley Medical Society met on May 26 at Morganton, N C, with the following guest speakers from the membership of this College

Dr John Russell Twiss (Fellow), New York City, "Differential Diagnosis and Clinical Management of Different Types of Gall-bladder Disease",

Dr Milton A Bridges (Fellow), New York City, "Dietary Management of Gall-bladder Disease",

Dr Isaac H Manning (Fellow), Chapel Hill, N C, "Hospital Saving Association of North Carolina"

Dr Samuel D Ingham (Fellow), Los Angeles, has been elected vice-president of the American Neurological Association

Under the presidency of Dr Julius H Hess (Fellow), the Chicago Medical Society held its annual banquet and the installation of new officers on June 17

Dr Ernest E Irons (Fellow) is retiring as dean of Rush Medical College to assume the title of professor of medicine Dr Irons will remain as chairman of the department of medicine Announcement has been made that the School of Medicine of the Division of Biological Sciences at the University of Chicago and Rush Medical College are now combined in one institution to be known as the Rush Medical College of the University of Chicago Undergraduate medical education will be continued at the west side school The medical schools are united in one departmental organization under the dean of the biological sciences Dr Emmet B Bay will act as associate dean on the west side It is said that the number of medical students will be greatly diminished during the next five years and graduate instruction will be introduced on an increasing scale, with the possibility that eventually graduate study may supersede undergraduate study entirely on the west side

Dr John Richards Aurelius (Fellow), St Paul, Minn, has been elected president of the Minnesota Radiological Society

Dr Thomas Hodge McGavack (Associate), San Francisco, has been appointed associate professor of medicine at the New York Medical College and Flower Hospital, beginning July 1

Dr William D Stroud (Fellow), Philadelphia, has been elected president of the Philadelphia Heart Association

Dr Joseph McFarland (Fellow), professor of pathology, University of Pennsylvania School of Medicine, retired June 30, having reached the age limit He will continue as professor of pathology in the Evans Dental Institute and the Veterinary School, both departments of the University of Pennsylvania

Dr Henry K Mohler (Fellow) has been promoted to associate professor of therapeutics at Jefferson Medical College, Philadelphia

Dr Guy W Wells (Fellow), Providence, R I, was elected secretary of the Rhode Island Medical Society at its annual meeting June 3

Dr Hugh S Cumming (Fellow), Washington, D C, is chairman of the Washington committee on arrangements for the Second National Conference on College Hygiene to be held in Washington, D C, December 28 to 31, under the joint sponsorship of the American Student Health Association, the National Health Council and the President's Committee of Fifty on College Hygiene It is announced that there will be no formal program with prepared addresses, but the work will be divided into five sections health service, health teaching, organization and correlation, special problems and relationship of college hygiene to teacher training and secondary education Dr Livingston Farrand, president of Cornell University, is chairman of the conference

Dr Ray M Balyeat (Fellow), Oklahoma City, Dr David J Davis (Fellow), Chicago, Dr Paul J Hanzlik (Fellow), San Francisco, Dr Russell L Cecil (Fellow), New York City, and Dr Cyrus C Sturgis (Fellow), Ann Arbor, are members of the College who appeared on the formal program of the fifteenth annual meeting of the Pacific Northwest Medical Association in Portland, Ore, July 8 to 11

Dr Virgil E Simpson (Fellow), Louisville, Ky, was guest speaker on May 19, 1936, at the meeting of the Southwestern Medical Society at Paducah Ky His subject was "The Physician, The Pharmacopoeia, Prescriptions and Philandering" Dr Simpson was also the guest speaker at the Harlan County Medical Society at Harlan, Ky, on May 30, 1936 Subject "The Social Security Act and the Medical Profession"

Dr Charles James Bloom (Fellow), Professor of Pediatrics, Post-Graduate School of Medicine, Tulane University of Louisiana, was one of the guest speakers of the State Medical Association of Texas before the Section on Medicine and Diseases of Children and the General Meeting, held in Houston, Texas, May 26, 27, 28, 1936

Dr Herbert T Kelly (Fellow), Philadelphia was guest speaker June 9, at the meeting of the Cumberland County (New Jersey) Medical Society The subject of his address was "Diabetes"

OBITUARIES

DR ALDEN H WILLIAMS

Dr Alden H Williams (Fellow), Grand Rapids, Mich , died June 10, 1936, of coronary occlusion, aged, 59 years

Dr Williams was born at South Gibson (Susquehanna County), Pennsylvania, and attended the Bloomsburg State Normal School He, however, became interested in medicine and entered the University of Michigan in 1894, receiving his medical degree in 1899 He did postgraduate work in Berlin, Germany, during 1907, and pursued several postgraduate courses, especially in radium and roentgen-ray therapy, in this country in later years During the World War he was in the Radiological Service of the U S Veterans Bureau He later became Chief of Staff of the Butterworth Hospital in Grand Rapids He was a past president of his county medical society, a member of the Michigan State Medical Association and a Fellow of the American Medical Association His interests were primarily in the field of radiology, and hence he was an active member and former president of the Radiological Society of North America, a member of the American Roentgen-Ray Society and other organizations in this field He became a Fellow of the American College of Physicians in 1922

DR ALANO E PIERCE

Dr Alano E Pierce (Fellow), Minot, N D , died March 14, 1936, of pneumonia, aged, 35 years

Dr Pierce was born at Dexter, Minnesota, April 22, 1900, he received the degree of Bachelor of Arts from the University of Minnesota in 1921, the degree of Bachelor of Science from the same institution, 1923, the degree of Bachelor of Medicine from the University of Minnesota Medical School in 1924, and his degree of Doctor of Medicine from the same institution in 1925 He did post-graduate study at the University of Vienna from February to November, 1926 He became Assistant in Medicine at the University of Minnesota Medical School in January, 1927 His internship was spent at the Minneapolis General Hospital He went to Minot, N D , in 1929, and became a member of the regular staff of the Trinity Hospital and became associated with the Northwest Clinic as Internist

He was a member of the Northwest District Medical Society, the North Dakota Medical Society and a Fellow of the American Medical Association He became a Fellow of the American College of Physicians on March 22, 1931

ANNALS OF INTERNAL MEDICINE

VOLUME 10

SEPTEMBER, 1936

NUMBER 3

THE PRESENT STATUS OF PERNICIOUS ANEMIA, EXPERIENCE WITH 600 CASES OVER EIGHT YEARS '

By CYRUS C STURGIS, F A C P, *Ann Arbor, Michigan*

INTRODUCTION

It is not the purpose of this article to present new and detailed data concerning pernicious anemia, but merely to give a number of conclusions dealing with some aspects of the etiology, diagnosis, prognosis and treatment of the disease which are based upon an experience with over 600 patients whom we have observed during the past eight years. The remarkable development of our knowledge of this condition during the last decade constitutes one of the most brilliant chapters in the history of medicine, for not only has a means been found of controlling a condition which had hitherto been considered fatal, but new fundamental facts of importance bearing on the physiology and pathology of many other blood diseases have been brought to light.

It has been firmly established, mainly through the investigations of W B Castle and his collaborators, that the cause of the anemia is a lack, or diminished amount, of an unidentified, enzyme-like substance, which is secreted by the mucosa of the stomach. This has been called the intrinsic factor which functions normally to control the rate of red blood cell production in the bone marrow. When there is a decreased amount or absence of this substance, the rate of blood production is diminished and an anemia results. Almost all students of the disease agree that the work of Castle is sound and has solved, at least in part, the problem of the etiology of the disease. His work has opened up an entirely new relationship between the gastrointestinal tract and blood formation which points the way to many new experimental approaches of studying blood diseases.

A detailed discussion concerning the diagnosis of pernicious anemia is not within the province of this paper, but several important diagnostic points should be emphasized which have arisen from a study of this group of patients. In the first place, not one single patient of this group has had free

* Presented at the Detroit meeting of the American College of Physicians, March 4, 1936

hydrochloric acid present in the gastric secretion, even following stimulation with histamine. Many thousand gastric analyses have been reported in the literature and in only an occasional case has "free" hydrochloric acid been reported. An achlorhydria, therefore, is essential to the diagnosis of true Addisonian anemia, and the presence of this acid in the gastric secretion practically eliminates it from consideration as a diagnostic possibility. It is impossible to say why several cases, of many, have been reported as having free acid, but two possibilities can be suggested: (1) that the patient did not have true pernicious anemia but some other type of macrocytic anemia (such as cirrhosis of the liver), and (2) that for some unknown reason free hydrochloric acid is actually present in the gastric secretions of an occasional patient with true pernicious anemia. Concerning the gastric secretions it can also be stated that in our experience free hydrochloric acid never returns when the patient has a complete hematopoietic remission although the gastric complaints almost always subside at this time. From a diagnostic standpoint it should also be emphasized that, in addition to the usual symptoms of any anemia, such as weakness, pallor, dyspnea and palpitation, there is another symptom which should almost always be present before the diagnosis of pernicious anemia can be made, and this is numbness and tingling of the hands and feet. This may be the initial symptom of the disease, but if not, it occurs at some time during its course in 90 per cent of the patients. If this complaint is lacking, it arouses a strong suspicion that the patient is suffering from some other variety of anemia than the pernicious type. Recurrent glossitis is also a symptom which has long been recognized as occurring in pernicious anemia but it has not been appreciated that it occurs in fully two-thirds of the patients. It likewise may be an inaugural symptom and precede the anemia by several years.

Brief reference only will be made to the changes in the blood. A careful study of our patients has confirmed the opinion of others that the most typical morphological change in the peripheral blood, at all stages of the anemia, is the presence of large oval red blood cells, or, as is said, a macrocytosis is present. This is more striking when the anemia is pronounced but it is also the last remaining evidence of abnormality as the blood reaches approximately normal limits. The predominance of small, rather than large cells, is almost conclusive evidence against an anemia of the pernicious type.

A sufficient period has now elapsed to permit a statement concerning the efficacy of various types of treatment. The different therapeutic agents which have been used are raw or cooked liver, liver extract and Ventriculin and liver and stomach combinations for oral use, and liver extract for intramuscular or intravenous injections. From our experience, it can be said that any one of these forms of treatment can usually control the anemia of pernicious anemia if sufficient quantities are given. It is our opinion, however, after giving thousands of treatments over a period of several years, that the ideal form of therapy is the intramuscular injection of liver extract. It has the following advantages

1 Gram per gram of liver, it is many times more effective when given parenterally than it is by mouth. It has also been observed that the oral treatment may increase the red blood cell count in some patients to a maximum level of slightly less than 4 million per cu mm, despite the administration of huge doses.

2 Local or general reactions have not been observed following its use. When liver extract is given intravenously it is highly effective, but following about 10 per cent of the injections there is a disagreeable reaction characterized by a chill, fever, and often nausea and vomiting. This type of reaction is not seen following intramuscular injections. In a very few instances the intramuscular injection has been followed by allergic manifestations such as urticaria. This has usually occurred, however, when the patient has previously been treated with intravenous liver extract which probably sensitized him to the product. This state of sensitivity was apparently transient for after a relatively brief interval it was possible to resume the intramuscular injections without the production of allergic signs. This is not a matter of great importance because it occurs only rarely and probably can be avoided if intravenous liver extracts are not given prior to the intramuscular type of medication.

3 Another advantage is that the intramuscular injection eliminates all problems of utilization of the product through incomplete absorption from the gastrointestinal tract and also that of inadequate storage in the body. For example, one patient whom we treated had a macrocytic anemia which probably resulted from a surgical procedure which anastomosed the jejunum to the transverse colon. This created a condition whereby a sufficient amount of the blood regulating substance was not absorbed from the gastrointestinal tract. Large amounts of liver extract and Venticulin by mouth were without effect in this patient, whereas the blood returned promptly to normal when liver extract was given intramuscularly. Also a macrocytic anemia may develop through the inability of the liver to store and properly metabolize the blood regulating substance. This probably occurs when the liver, which is the main storage depot in the body for the blood regulating substance, is extensively damaged, such as it may be in cirrhosis. Intramuscular liver extract is efficacious under these circumstances when oral medication is less effective.

4 The treatment by intramuscular injections is regarded by most of our patients as the most convenient form of therapy as the blood may be maintained at a normal level by one injection weekly and ordinarily no other medication is required.

The only objections to the intramuscular treatment are (1) Individuals who live in isolated communities find it inconvenient or impossible to visit the physician at regular intervals for the injections. An attempt has been made, with only partial success, to instruct patients in the method of administering their own injections. (2) The expense of treatment may be greater, or less, than that with oral types of medication but this depends

largely on the charge which the physician makes for giving an intramuscular injection

What should be the ideal dosage of intramuscular liver extract? This is a difficult question to answer precisely, for the following two reasons (1) Pernicious anemia may be regarded as a disease with a deficiency which is probably relative rather than absolute. It is logical, therefore, to consider that some patients will require a greater dosage than others. (2) The concentration of liver extracts which are commercially available varies widely in the amount of active principle. For example, one manufacturer states that 1 c c is derived from 100 c c of liver, whereas another states that 2 c c are derived from 10 grams of liver.

For these reasons our advice to physicians in answer to this question is as follows. Give a variety of liver extract which is (1) clinically tested, (2) use the dose advised by the manufacturer, (3) control the dosage by making frequent red blood cell counts.

The latter statement should be strongly emphasized, for the level of the red blood cells is the best single criterion concerning the effectiveness of the treatment and it should be determined systematically and periodically in every patient with pernicious anemia who is being treated. A sufficient quantity of the material should be given to keep the red blood cells at a level between 4.5 and 5.0 millions per cubic millimeter. If a patient's blood has reached normal and for any reason the type of medication or the dosage is changed, then a red blood cell count should always be made at monthly intervals thereafter for several months to insure that adequate therapy is being administered.

The intramuscular preparation with which most of the patients of this series have been treated was standardized on the basis that 2 c c are derived from 10 grams of liver. The initial dosage of this preparation in a patient who has pernicious anemia should be 12 to 16 c c weekly in doses of 4 c c at a time, until the blood reaches normal. It is known that the red blood cell count with optimum treatment will increase at the rate of about 500,000 red blood cells per cu mm per week and, therefore, if the initial level of the red blood cells was 1 million per cu mm, it should reach normal in about 8 weeks. After the blood reaches normal, it has been observed that about 4 c c weekly, given at one dose, are required to maintain it at this level, although the limits of the maintenance dosage vary between 2 and 6 c c weekly.

Many times the question has been asked, "Is it possible to maintain the blood of a patient with pernicious anemia within normal limits indefinitely and the individual be kept in good health so that he can live out his normal span of life?" The answer is that he probably can, provided (1) Extensive cord lesions are not present when treatment is begun, (2) If an adequate amount of potent anti-pernicious anemic material is given, which requires the closest cooperation between physician and patient. A great majority of the present day failures in the treatment of pernicious anemia

are due to (1) The failure of the patient to appreciate that the therapy of pernicious anemia is merely one which controls the disease and does not eliminate its fundamental cause. It is necessary, therefore, that potent medication, in one form or another, be continued throughout the remainder of the patient's life, (2) The failure on the part of the physician to appreciate that the patient must remain under his observation, more or less continuously, for an indefinite period.

Perhaps the most important therapeutic problem in the field of pernicious anemia at present is the management of the spinal cord changes, and a great many opinions have been expressed concerning this. It is well recognized that the pathologic changes in the central nervous system, which occur as a complication in a fair proportion of patients with pernicious anemia, consist of actual degeneration of nerve fibers in the posterior and lateral columns of the cord which results in an ataxia with varying degrees of spastic paraplegia. As the process develops, there is a loss of control of the sphincter of the bladder with retention of urine, a resultant cystitis, and, if the condition progresses, an ascending pyelitis, with abscesses of the kidney, septicemia, bronchopneumonia and death. While anti-pernicious anemic therapy produces striking effects as far as the blood is concerned, the results attained in treating the central nervous system lesions are controversial. It has been our experience that there is often striking subjective improvement but that objective evidences of this occur in only a small per cent of the patients. On the other hand, patients have been observed who have made an unbelievable recovery. One woman of 61, with red blood cell count of 1,000,000 per cu mm, who was confined to bed with a well advanced combined degeneration of the cord, intense infection of the urinary tract, extensive decubitus ulcers, and incontinence of urine and feces, is now able to walk unassisted and does all of her own housework including the family washing. This improvement has been maintained over a period of four years.

The question has been asked, whether if a patient with pernicious anemia who has no evidence of cord changes is treated in such a manner that the blood is maintained at a high normal for an indefinite period, are cord changes likely to develop. The opinion of most observers is that this is unlikely, although it must be admitted that this question must remain unanswered until sufficient time has elapsed to give the facts for a statement which is based on actual observation over a long period of years. In our group of patients this has not occurred in a single patient during a period of eight years.

The present treatment of the cord changes, in addition to the management of the urinary infection and decubitus ulcers which may be present, is not complicated. It consists (1) in administering treatment which will cause the blood to return to a high level of normal and maintaining it there indefinitely. (2) Physiotherapy, which consists mainly in active motion produced by the patient's attempts to walk when supported by attendants,

(3) Reeducation in coordination of the muscles of the legs, and teaching the patient to use his eyes in guiding his walking attempts, as the sense of motion and position of his legs is, of course, usually destroyed by the lesions in the posterior columns of the cord

In addition to anti-pernicious anemia therapy, there are several minor therapeutic adjuncts which have been used by some physicians in treating pernicious anemia, although their value has not been definitely established. For example, should or should not dilute hydrochloric acid be given along with the liver therapy? It is true that all of these patients have an achlorhydria and in our experience the ability to secrete acid never returns when the blood reaches normal. In most instances, all gastrointestinal complaints disappear at this time but in a few patients they persist. In those in whom they do persist, dilute hydrochloric acid has been given and many times the complaints have disappeared. There are several possible explanations of this, as follows: (1) They might have disappeared without the hydrochloric acid therapy, (2) The psychic effect of giving the acid may have played an important rôle, (3) The hydrochloric acid might have had a truly beneficial effect.

In those patients with pernicious anemia in whom the gastrointestinal symptoms persist after the blood returns to normal, two possibilities should be considered: (1) the patient should be carefully studied to be sure a complicating gall-bladder condition is not present and this is not uncommon in patients with pernicious anemia, (2) dilute hydrochloric acid therapy may be given a therapeutic trial as it can do no harm and it might do some good.

Iron has been recommended by some as a beneficial drug in this disease. It certainly has no specific effect, but its use should be considered where certain conditions prevail, as follows: (1) When liver or stomach treatment is given, the red blood cell count always increases more rapidly than does the hemoglobin, as a result the color index always falls below 1.0. If this persists for a period of weeks, iron therapy, in the form of Reduced Iron, 0.5 gm t.i.d., is indicated. (2) A few patients have been observed who have had their condition complicated by chronic bleeding, usually from hemorrhoids. Then, of course, iron in the above dosage is clearly indicated.

Special diets and the addition of concentrated vitamins are rarely required in the treatment of pernicious anemia because the patient's appetite is so stimulated by the anti-anemic therapy that a large amount and variety of food are demanded. Occasionally a patient has been observed who apparently had a combination of pernicious anemia and a nutritional anemia. The diet under these circumstances is usually so obviously unbalanced that it is at once apparent and it is easily corrected by giving an ordinary diet.

The Prognosis This topic has been discussed briefly earlier in this article. Further information concerning this may be obtained by a consideration of the fatal cases in our series of 600 patients. During a period of one to eight years, slightly over 10 per cent of these patients died, and

approximately one-half of them succumbed to complications associated with lesions of the central nervous system. It is only fair to say, however, that almost all of this group either had advanced cord lesions when they were first observed, or that they failed to carry out the treatment as we had directed. Furthermore, many of these patients were treated before the parenteral method of administering liver was available. One can only speculate as to how many of them would have survived if they had been seen early in the course of the disease and if they had been intensively treated with intramuscular liver extract injections.

The remaining one-half of the fatal cases died of a variety of diseases which are not uncommon causes of death in this age group and the fatal conditions can only be regarded as having a coincidental association with pernicious anemia. The most common causes of death in this group were cardiac disease, hypertension and apoplexy, operations and accidents, pneumonia and malignancy. It is interesting to note that apparently none of these patients died of anemia per se, as their red blood cell counts were not reduced to a seriously low level when they were last observed.

In conclusion it may be said that pernicious anemia can no longer be looked upon as a disease which is necessarily fatal provided appropriate treatment can be applied, and, furthermore, in the near future there will undoubtedly be greater improvement and refinement of our present day methods of treatment.

VASCULAR PHYSIOLOGY AND CLINICAL MEDICINE

By EUGENE M. LANDIS, F A C P, *Philadelphia, Pennsylvania*

WHEN William Harvey first described the circulation of the blood over 300 years ago his observations were necessarily limited to the grossly visible portions of the circulatory system,—to the heart, arteries and veins. His evidence for a completely closed circulation, even on this basis, was so conclusive that the capillary portion of that circulation could be taken practically for granted. It was, in fact, 50 years before the capillaries themselves were observed under the microscope.

It seems as if investigation of capillary physiology has never been able quite to overcome this initial handicap of half a century. The heart and larger vessels received the painstaking attention of those interested in circulation, while the more minute parts of the vascular tree were, relatively speaking, neglected. This seems surprising because, from the functional standpoint, the heart, arteries and veins are subsidiary to the capillaries which have correctly been called "the workshop of the body."

Our present knowledge concerning this "workshop of the body" is the outcome of mutual stimulation and aid in the fields of clinical medicine and vascular physiology. For instance, the occurrence of edema, an outstanding clinical problem even before the time of Galen, stimulated earlier physiologists to ponder on the mechanism which controls the transportation and distribution of fluids throughout the body. In the normal individual the volume of tissue fluid suffers only transitory and relatively small changes despite wide variations in water intake. In patients with a tendency toward edema formation, on the contrary, the copious ingestion of water usually increases the normally meager amount of tissue fluid until clinical edema appears. They suffer apparently from a more or less serious breakdown of the normal mechanism of fluid transport.

The first reasonably complete hypothesis explaining the maintenance of equilibrium between blood and tissue fluid under diverse conditions was advanced by Starling,¹ a physiologist, in 1896 and was later expanded to explain tentatively the pathogenesis of edema. Starling called attention to the fact that those substances (such as salts, urea, creatinine, etc.) which pass easily through the capillary wall and are present in approximately equal concentrations in blood plasma and tissue fluid, cannot exert an osmotic pressure across the capillary wall and should not, therefore, affect the distribution of fluid except very temporarily. The plasma proteins, however, by reason of their greater molecular dimensions, are retained more or less efficiently by the capillary wall and can develop an osmotic pressure, amounting in man to approximately 26 mm. of Hg. This colloid osmotic pressure

of the blood, if unopposed, would filter fluid into the capillary blood from the tissue spaces. If this is true the relative constancy of blood volume and tissue fluid volume must depend primarily upon the balance between capillary blood pressure and the colloid osmotic pressure of the blood. This ingenious concept, though theoretically sound, was still open to criticism owing to the difficulties surrounding the measurement of capillary blood pressure.

In 1917 Epstein,² a clinician, emphasized the importance of hypoproteinemia in the pathogenesis of nephrotic edema. According to Starling's view this type of edema could be explained logically by the general lowering of colloid osmotic pressure which, in association with a normal capillary blood pressure, would favor filtration of fluid and, at the same time, hinder absorption from the tissue spaces.

War edema, associated with protein starvation, was also found during this period to be accompanied by hypoproteinemia, the edema disappearing when the plasma protein percentage rose to normal. Further clinical study by Krogh,³ Schade,⁴ Govaerts,⁵ Meyer⁶ and others verified the importance of hypoproteinemia in some types of edema, but showed that in other types the plasma protein percentage was usually within normal limits. The general problem of normal fluid balance and the clinical problem of edema then seemed too complex to be explained by simple physical principles.

Until rather recently the capillaries were generally believed to be inert, thin-walled tubes serving to conduct blood through the tissues in whatever quantity the arterioles might supply. About 1920 the work of Krogh,³ a physiologist, and of Lewis,⁷ a clinician, supplied from two directions impressive evidence showing that the capillary vessels are independently contractile and that they are capable of responding individually in a delicate manner to the circulatory needs of the immediately adjacent tissues. Even so the great transporting medium, the blood stream, is still separated from almost all the tissues it serves by a single layer of endothelial cells which form the walls of the capillary vessels. Obviously the interchange of substances between blood and tissues must depend fundamentally upon the properties of this membrane in association with the physical forces controlling the flow of blood past the membrane.

The primary factors involved in a quantitative study of the movement of fluid through a membrane are (a) the total area of filtering surface available, (b) the properties, particularly the permeability, of the membrane itself, and (c) the pressures exerted on the fluid both inside and outside the membrane.

The collective area of capillary wall available for fluid interchange is relatively enormous. Krogh³ estimated that the total surface of capillary wall in the body of an average-sized man must exceed 6,300 sq meters or 68,000 sq feet. In other words the total collective area of capillary endothelium in the adult human body can be visualized as a microscopically thin membrane three feet wide and over four miles long. In the capillary net-

VASCULAR PHYSIOLOGY AND CLINICAL MEDICINE

of the blood, if unopposed, would filter fluid into the capillary blood from the tissue spaces. If this is true the relative constancy of blood volume and tissue fluid volume must depend primarily upon the balance between capillary blood pressure and the colloid osmotic pressure of the blood. This ingenious concept, though theoretically sound, was still open to criticism owing to the difficulties surrounding the measurement of capillary blood pressure.

In 1917 Epstein,² a clinician, emphasized the importance of hypoproteinemia in the pathogenesis of nephrotic edema. According to Stirling's view this type of edema could be explained logically by the general lowering of colloid osmotic pressure which, in association with a normal capillary blood pressure, would favor filtration of fluid and, at the same time, hinder absorption from the tissue spaces.

War edema, associated with protein starvation, was also found during this period to be accompanied by hypoproteinemia, the edema disappearing when the plasma protein percentage rose to normal. Further clinical study by Krogh,³ Schade,⁴ Govaerts,⁵ Meyer⁶ and others verified the importance of hypoproteinemia in some types of edema, but showed that in other types the plasma protein percentage was usually within normal limits. The general problem of normal fluid balance and the clinical problem of edema then seemed too complex to be explained by simple physical principles.

Until rather recently the capillaries were generally believed to be inert, thin-walled tubes serving to conduct blood through the tissues in whatever quantity the arterioles might supply. About 1920 the work of Krogh,³ a physiologist, and of Lewis,⁷ a clinician, supplied from two directions impressive evidence showing that the capillary vessels are independently contractile and that they are capable of responding individually in a delicate manner to the circulatory needs of the immediately adjacent tissues. Even so the great transporting medium, the blood stream, is still separated from almost all the tissues it serves by a single layer of endothelial cells which form the walls of the capillary vessels. Obviously the interchange of substances between blood and tissues must depend fundamentally upon the properties of this membrane in association with the physical forces controlling the flow of blood past the membrane.

The primary factors involved in a quantitative study of the movement of fluid through a membrane are (a) the total area of filtering surface available, (b) the properties, particularly the permeability, of the membrane itself, and (c) the pressures exerted on the fluid both inside and outside the membrane.

The collective area of capillary wall available for fluid interchange is relatively enormous. Krogh³ estimated that the total surface of capillary wall in the body of an average-sized man must exceed 6,300 sq meters or 68,000 sq feet. In other words the total collective area of capillary endothelium in the adult human body can be visualized as a microscopically thin membrane three feet wide and over four miles long. In the capillary net-

work one cubic centimeter of blood is exposed to a filtering surface of 7,300 sq centimeters or over 7 sq feet. Obviously very rapid interchanges are favored by areas of this magnitude.

In the second place, rapid interchange of water and dissolved salts is aided by the inherent properties of the capillary endothelium which is far more permeable than other living membranes so far studied quantitatively. Under comparable conditions⁸ water would pass through the frog's capillary wall three thousand times more rapidly than through the surface membrane of a typical cell and over one hundred times more rapidly than through the membrane of the human erythrocyte.

The significance of this extensive filtering area combined with great permeability can be expressed by a calculation which is admittedly approximate but illustrates the order of magnitude of possible effects. Assuming that the capillary wall of man is as permeable as the frog's capillary wall, the total plasma volume of a man could be filtered through his calculated 68,000 sq feet of endothelium within 10 seconds at a capillary pressure of only 10 mm of Hg if there were no force retaining fluids within the blood capillaries. Normally the activity of the vasomotor system prevents the entire peripheral vascular bed from opening simultaneously. In addition, the plasma proteins, by their colloid osmotic pressure, limit the loss of fluid from the blood stream. Only in widespread injury of the vascular endothelium would it be possible for fluid to leave the vascular system at such a deleteriously rapid rate.

Quantitative studies of the third factor, namely capillary blood pressure, offer some technical difficulty. Capillary blood pressure has been measured by many indirect methods, no one of which is entirely free from criticism. The estimates of pressure thus obtained by different observers ranged from far below to far above colloid osmotic pressure. Plethysmographic methods of determining the relation between capillary blood pressure and fluid movement require using masses of tissue containing large numbers of capillaries. The interpretation of these results is often difficult because of changing diameter, pressure and rate of flow in the separate vessels composing the capillary network. These variables can be reduced in number and more adequately controlled by studying single capillaries directly—thus limiting observations to what is, in fact, the smallest unit of the circulatory system.

To measure venous blood pressure directly it is necessary to use a needle small enough to be inserted easily into a vein, similarly, to measure capillary blood pressure directly the puncturing needle must be thinner than a single capillary. Chambers,⁹ an anatomist, had devised delicately adjustable micro-manipulators for the microscopic dissection of single cells. Using this technique and micro-pipettes measuring four to eight thousandths of a millimeter across at their tips it was possible, under the microscope, to pierce single capillaries at various locations.¹⁰ Capillary blood pressure could then be measured repeatedly for minutes, or with luck, for hours by determining

the pressure that must be exerted upon the fluid in the pipette to balance exactly the blood pressure in the capillary under observation

From a large number of single determinations in the main anatomical subdivisions of the vascular tree it became evident that average blood pressure in the arteriolar portion of the capillary network is measurably higher than that in the venous portion. Such a gradient of capillary blood pressure was observed in the four species studied (frog, rat, guinea pig and man) but the absolute level of pressure at which this gradient is maintained was found to differ considerably according to species. In the frog, for instance, arterial capillary pressure amounts to 14 cm water, venous capillary pressure to 10 cm water¹⁰. For man these figures are 45 and 22 cm respectively¹¹. If Starling's original hypothesis is correct the colloid osmotic pressure of human and amphibian plasma should show corresponding differences. In general this is the case since frog plasma has a colloid osmotic pressure between 7.5 and 13.0 cm water, human plasma about 36 cm water. The rat and guinea pig occupy an intermediate position in both respects¹². These findings are in accord with the concept that filtration favored in the arteriolar part of the capillary network will be balanced by absorption in the venous part of the capillary network.

Further development of micro-injection methods made it possible to measure the filtration and absorption of microscopically small volumes of fluid by single capillaries of the frog's mesentery¹³. It was then found that the rate and direction of fluid movement through the endothelium depended upon the relation between capillary blood pressure and the colloid osmotic pressure of the plasma,—supplying direct evidence that the capillary wall acts as a passive, though highly permeable, membrane. If capillary pressure is greater than the colloid osmotic pressure of the plasma, fluid is filtered into the tissue spaces. If capillary blood pressure is lower than the colloid osmotic pressure of the blood, fluid is absorbed from the tissue spaces. The rate of filtration or absorption is directly proportional to the difference between capillary blood pressure and the colloid osmotic pressure of the plasma. In the capillary network as a whole these two forces are normally approximately equal so that, on the average, filtration and absorption balance.

In human subjects the filtration produced by elevating capillary pressure can be demonstrated by enclosing the forearm in a plethysmograph specially constructed to determine changes in the volume of extravascular fluid, or in other words, the volume of edema fluid produced by venous congestion. Measured in this way the rate at which fluid filters into the tissue spaces is, above a certain minimal level, directly proportional to venous pressure¹⁴. Owing to the large area of endothelium and its high permeability to water and salts, changes in the volume of tissue fluid can occur with great rapidity. When venous pressure is raised to 80 mm of mercury the initial rate of filtration is 11 c.c. per 100 c.c. of forearm tissue per hour¹⁴. Studies of the blood revealed that 100 cubic centimeters of arterial blood can lose as much

as 20 cubic centimeters of fluid in passing through the capillary bed of the forearm during such high-grade venous congestion¹⁵

If this initial rate of filtration were to continue unchanged, edema would be produced in the normal subject within an hour. Fortunately the tissues resist, at least temporarily, the distortion which the accumulation of extravascular fluid produces as it forces the tissue elements apart¹⁴. This tissue pressure, since it partially neutralizes high capillary pressure, plays an important, though temporary, part in preventing the development of edema.

Excessive filtration of fluid may be produced also by reducing the colloid osmotic pressure of the blood. Plethysmographic studies on the forearms of normal human subjects indicated that *lowering* the colloid osmotic pressure of the blood favors the filtration of fluid into the tissues to the same degree quantitatively as *raising* venous pressure¹⁶. In animals, Leiter¹⁷ and others produced edema by lowering experimentally the plasma protein percentage, thus simulating the hypoproteinemic edema of nephrosis or malnutrition.

The preceding discussion has summarized physiological evidence that the normal capillary wall exhibits the properties of an inert (that is, non-secreting) membrane which is practically impermeable to the plasma proteins. Chemical studies by Loeb¹⁸ and others compared the concentrations of electrolytes in edema fluid and blood plasma without detecting any chemical evidence that the capillary wall in patients with edema behaved differently from celloidin membranes of similar permeability. Other studies¹⁵ of the protein in edema fluid of patients and in the capillary filtrate of normal subjects showed that these fluids contained in general less than 0.3 per cent protein, while the plasma from which the fluid filtered contained from 6 to 7 per cent protein. The normal capillary wall in resting tissues is about 95 per cent efficient in retaining the plasma proteins of the circulating blood. Muscular activity,¹⁹ anoxemia²⁰ and venous congestion¹⁵ reduce the efficiency of the endothelium in this respect.

Capillary injury of any type impairs or destroys this normal impermeability to protein. The gross systemic effects of widespread endothelial damage were recognized clinically even before war injuries directed the attention of physiologists and physicians to the shock syndrome and its relation to the capillary circulation. The local effects of vascular injury may be demonstrated and measured quantitatively, again by studying microscopically the ultimate functional unit of the circulatory system. Certain colloidal dyes perfused through single capillaries are retained by the normal endothelium. If the capillary is injured mechanically by light pressure with a microscopic glass rod the wall becomes highly permeable. The colloidal dye passes very rapidly through the injured endothelium though still retained by the adjacent normal endothelium²¹. After mechanical or chemical injury erythrocytes originally separated by plasma are concentrated and compressed into solid masses in the injured regions, indicating that plasma as a whole, including protein, filters rapidly through the damaged endo-

thelium In such capillaries the plasma proteins lose their power of retaining fluid since they pass easily through the injured wall and can exert no colloid osmotic pressure Fluid then filters into the tissue spaces approximately seven times more rapidly than normal and at capillary pressures which under normal conditions would bring about absorption¹³ In view of this seven-fold increase in permeability the rapidity with which shock or inflammatory edema develops does not seem so extraordinary

TABLE I

Factors Favoring Edema Formation	Clinical Examples
A Primary	
1 Elevated capillary pressure	1 (a) External pressure on veins (b) Thrombophlebitis (c) Cardiac edema with venous congestion
2 Lowered colloid osmotic pressure	2 (a) Nutritional edema (b) Nephrotic edema (c) Cardiac edema, late stages with malnutrition
3 Damage to capillary wall	3 (a) Inflammatory edema (b) Nephritic edema (c) Cardiac edema (?), chronic anoxemia
4 Lymphatic obstruction	4 (a) Lymphedema (b) Cardiac edema with venous congestion
B Contributory	
5 Low tissue pressure	5 Edema of periorbital tissues and genitalia
6 High salt intake	6 Increases edema if water is available
7 High fluid intake	7 Increases edema if salt is available
8 Warm environment	8 (a) Heat edema (b) Increases all types of edema
9 Disturbed innervation	9 (a) Tropho edema (b) Unilateral edema in hemiplegia

By combining available clinical and physiological data the factors concerned in the pathogenesis of edema may be summarized tentatively under two heads (table 1) Those listed as primary are fundamental since each factor in sufficient grade can produce clinical edema unaided by other forces The contributory factors on the other hand do not themselves produce edema but modify the severity or distribution of edema produced by one of the primary causes There are undoubtedly other factors in addition to those listed since it has been observed that in nephrosis a copious diuresis may begin spontaneously and massive edema can disappear even while the plasma proteins are still extremely low Unravelling the mechanism responsible for this spontaneous resolution of edema may well provide a diuretic more physiological and more constantly effective than those now at our disposal clinically

The maintenance of fluid balance, with all its physical niceties of adjustment, is only one of the functions of the circulatory system. In certain tissues the rate of blood flow must at times be increased to 20 or 30 times the resting rate in order to compensate for tissue activity, change in posture, temperature control or local inflammatory reactions.

Capillary blood pressure and flow, as might be expected, vary together over very wide ranges.¹² Blood pressure changes in the same capillary from moment to moment and may differ widely in adjacent capillaries arising from the same arteriole. For example, chemical injury to the frog's web produces reflex vasodilatation, increased rate of blood flow and a conspicuous rise in capillary blood pressure.²² Similarly, in man, heating the skin at the base of the finger nail induces hyperemia and with it a striking rise of capillary blood pressure in the heated area.¹¹ Cold, on the contrary, produces an initial vasoconstriction and decrease in capillary pressure followed after a few minutes by local reactive vasodilatation, hyperemia and elevation of capillary blood pressure. Raynaud's disease is a condition in which a more or less prolonged period of vasospasm is followed by arterial relaxation and reactive hyperemia. During the period of spasm capillary blood pressure is habitually low, e.g. 7 mm Hg, but with vasodilatation rises for brief periods to exceed 40 mm Hg.²³ Spontaneous variations in peripheral blood flow and capillary blood pressure are, under proper conditions, equally large. Clinical medicine uses this wide physiological range of peripheral blood flow to differentiate those peripheral vascular diseases characterized by pure vasospasm from those associated with organic or structural diseases of the arterial wall.

The development of simple thermo-electric methods of measuring skin temperature under standard conditions has made it possible to estimate deficiencies of blood flow and to differentiate the ischemia of vasospasm from that of obliterative arterial disease. Complete dilatation of structurally normal blood vessels elevates skin temperature to levels which are constant enough to be used as a practical estimate of the maximum increase in peripheral blood supply that can be produced by suitable therapeutic measures. The diagnostic methods available for producing temporarily maximal blood flow in the extremities are numerous,—novocaine block of peripheral nerves, general or spinal anesthesia, paravertebral injection of novocaine, or warming the body.²⁴ If skin temperature can be elevated by any one of these methods to 30.5° C or more, significant organic vascular occlusion is absent. The diagnoses to be considered are by this test limited to those conditions due principally to vasomotor disturbances.

If, during a vasodilator test, skin temperature rises only to 26 or 27° C, structural disease of the arterial wall is present in slight grade, and the organic vascular conditions must be considered. A partial vasodilator response reveals also that moderate arterial dilatation is still possible and considerable assistance may be expected from vasodilator agents including heat, typhoid vaccine, drugs and sympathetic ganglionectomy. It should

be mentioned that even in uncomplicated Raynaud's disease cervico-dorsal sympathetic ganglionectomy has been followed in some instances by perplexing recurrence of vasospasm. Smithwick, Freeman and White²⁵ have found the denervated vessels of these patients to be abnormally sensitive to epinephrine, thus extending to human beings the results of earlier studies by Langley, Meltzer and Elliott, on the abnormal physiology of mammalian blood vessels after degeneration of the post-ganglionic sympathetic fibers.

In advanced organic vascular disease the physiological variability of blood flow in the extremities may be almost or completely absent. At this stage abolition of vasoconstrictor tone fails to elevate skin temperature. Those therapeutic procedures which depend on vasodilatation cannot be expected to increase blood flow significantly. For treating patients with advanced organic vascular obstruction it was suggested simultaneously on physiological grounds by Landis and Gibbon,²⁶ and on clinical grounds by Reid and Herrmann²⁷ that varying the air pressure about the affected extremity might aid blood flow by physical means. Objective studies indicated that blood flow could be increased at least temporarily in this way, even though advanced organic arterial occlusion prevented increasing blood flow by other methods.

From this brief review of the clinical problems of edema and peripheral vascular disease it seems evident that the recent rapid advances in theory and practice have arisen from the interplay of thought and observation simultaneously in the fields of vascular physiology and clinical medicine. Theory, experiment, observation and conclusion follow logically though their origins include laboratory and clinic. The respective contributions of physiology and medicine are not in any sense separable, on the contrary, their interdependence is striking.

ERRORS IN CARDIOVASCULAR ROENTGEN-RAY INTERPRETATION

By HUGO ROESLER, M D , *Philadelphia, Pennsylvania*

ERRORS in cardiovascular roentgen interpretation are due mostly to the following reasons. Insufficient knowledge of the theoretical and applied physical principles of the roentgen-rays, insufficient knowledge of anatomy, physiology and pathology of the cardiovascular system, and deficiency in the technical outfit and procedures.

Facts which pertain to the roentgenological study may not be registered and therefore the first part of the report, which should contain all findings, is inadequate. Or facts are registered but interpreted erroneously and therefore the second part of the report, which should contain the conclusions, is inadequate.

The limitations of the roentgenological method permit one to analyze and evaluate only certain aspects of the cardiovascular system, and these are not in all cases necessarily the most significant.

Every study should start with fluoroscopy. A film record in its frozen aspect expresses the statics, while fluoroscopy expresses the dynamics of the situation. Adaptation of the retina is of utmost importance, it increases in darkness in the form of a logarithmic curve, the knee of which is not reached until 15 to 20 minutes have elapsed. Information as to detail is enhanced by excluding much of the secondary radiation. This is done by using a small shutter. This may be the only means which will permit detection of small lime salt deposits in the heart or in the pericardium.

Since we are dealing with objects in motion, the exposure time of the film, taken at the conventional distance of 200 cm, should not be more than one twenty-fifth of a second. If one is dealing scientifically with heart size or when the amplitude of the pulsations is to be measured, it is indispensable to know in which phase of the cardiac cycle the roentgenogram was made, methods must also be employed to always guarantee the same phase of respiration. Ordinary teleroentgenograms do not represent a projection of the true size of an object, the degree of magnification is determined by the object-film distance, by the size of the object and by the target-film distance. The magnification of the projection of an average normal heart amounts to approximately 10 per cent.

Orthodiagraphy requires great accuracy, the silhouette should be drawn in diastole and during quiet, shallow respiration. Drawings and films should preferably not be made at the end of deep inspiration, a distortion of the silhouette results and even an involuntary Valsalva test may be produced.

* Read at the Detroit meeting of the American College of Physicians, March 3, 1936.
From the departments of Roentgenology and Medicine, Temple University Hospital, Philadelphia, Pennsylvania.

Such chest films taken in deep inspiration have been partly responsible for the sweeping statements as to the smallness of the heart in the presence of tuberculosis of the lungs

Orthodiagraphic tracings can hardly ever be accepted as records for purposes of comparison and teleoroentgenograms only rarely so, unless certain standards are preserved. They are: The target-film distance must be maintained inviolate, the target, the mid-line of the patient and the mid-line of the film must be accurately centered, the chest must not undergo any change in position, either in the sense of (a) rotation along its long axis, or (b) increased lordosis or kyphosis. Furthermore, the position of the diaphragm and the phase of the cardiac cycle must be identical.

Roentgenology furnishes convincing evidence that there is no single type of visceral anatomy and physiology. Normality, as a statistical concept, refers to the average or central values on the curve of variability. Because of the range of variation, errors in interpretation occur and organic disease is occasionally diagnosed when none is present, while such disease is not recognized when it exists. This refers especially to the extreme constitutional types. In the hypersthenic type, enlargement of heart and aorta or aortic configuration is liable to be diagnosed while in the hyposthenic type, smallness of the heart or mitral configuration is often mentioned. The influence of the filling of the heart on its size is perhaps underrated and the constitutional factor often too greatly stressed, certain small hearts are small only when the examination is limited to the vertical position. Normal hearts show definite anatomical variations in their general shape independent of their volume. It is well to know that the size of the aorta increases continuously with age and the direction of the aortic arch changes. Elongation, dilatation, and tortuosity have been diagnosed and attributed to atherosclerosis where only anatomical-physiological changes due to age were present. Atherosclerosis, on the other hand, may be present without appreciably altering the size and shape of the vessel.

From the outer left caudal surface of the pericardium, a triangular ligamentous fold extends to the diaphragmatic and mediastinal pleura, after puberty, fat is found along its anterior surface. Ordinary chest films often do not permit differentiation of the heart shadow proper from this anatomical formation which, when included in the cardiac measurement, results in erroneously high figures.

The roentgenological lung pattern is fundamentally caused by the blood-filled vessels. They appear partly in length and partly in cross-section. These structures, especially when blurred because of improper exposure technic, have been erroneously interpreted as pulmonary fibrosis. The following three abnormal appearances of the lung fields have often been misinterpreted. First. The active, hypertensive, interstitial and intra-alveolar edematous transudation, of a subacute type and predominantly central location which occurs especially in the course of acute or chronic azotemic cardio-renal disease. This condition has not the appearance of vascular dilatation,

and should therefore not be designated as congestive failure, and it is not inflammatory in type though it has been called pneumonic infiltration. Second A passive, hypertensive, arterial, venous and lymphatic enlargement, with interstitial reaction, of a chronic type and diffuse appearance, which occurs most typically in the presence of chronic mitral valvular lesions. It has been confused with fibrosis, milary tuberculosis and carcinomatous disease of the lymphatics. Third An active, hypertensive enlargement of the pulmonary arterial tree, as it is observed in instances of pulmonary atherosclerosis, arteriosclerosis and syphilitic arteritis, or in the course of pulmonary artery orifice regurgitation or interatrial septal defect. It is often described as evidence of congestion or infiltration and the unduly outstanding shadows of the main branches have been interpreted as tumors, especially of the metastatic type.

One must realize, in studying the pulsations, that they express a combination of volumetric, pressure and displacement changes. Only the outer pulsations of the silhouette can be studied under normal conditions and the pulsatory movements of the following structures are not visible, under normal conditions. A portion of the anterior heart surface, the atrio-ventricular septum (the piston-like movement as contrasted with the margin movement), the first portion of the ascending aorta in its whole circumference, the mesial contours of the distal portion of the ascending aorta, of the arch of the aorta and of the pulmonary artery, a considerable portion of the lower heart border. The visible pulsations of the aorta do not express exclusively actual volumetric changes but represent position changes of the whole vessel. The actual amplitude of the movement is fully registered only when its direction is at right angles to the direction of the central rays. It may be added that the roentgenological ventricular systole, in the conventional sense, represents the emptying periods of the ventricular systole.

Much information is missed without a fluoroscopic study. The absence of movements along the silhouette border is of significance in the diagnosis of myxedema, cardiac tamponade and certain types of chronic adhesive-constrictive pericardial disease. However, it should be pointed out that in other types of the latter lesion, a great amplitude can be observed, especially with a rapid diastolic outward movement and usually associated with marked chest wall pulsations. They are found first when there are external adhesions fixing heart and pericardium to the anterior chest wall, and second when the base of the heart is fixed, then the longitudinal contraction of the ventricular cone is interfered with and this reduction in movement is compensated for by increased marginal excursions. A diminution of pulsations along the left lower heart border is observed whenever the latter is formed by the right ventricle. One observes in the course of severe emphysema an inspiratory distention, followed by an expiratory diminution of the silhouette more marked on the right side. Intracardiac calcifications in the atrio-ventricular septum and in the valve rings are sometimes diagnosed only by observing the characteristic dancing movements. The presence of even a

small amount of air or gas along the mediastinal surface of the lung is immediately diagnosed by the large, flopping pulsation of the silhouette border showing also a vertical, "heaving" component

An aneurysm of the ventricular muscle can sometimes be diagnosed only by observing abnormal pulsations, namely the outward movement during systole (simultaneously there appears a clinical thrust) or a synchronous or paradoxical movement as compared with the adjacent cardiac contours. The right ventricle may form a greater portion of the left silhouette contour and increased pulsations are noted in the presence of increased output (tricuspid or pulmonary regurgitation). The concomitant aortic pulsations remain small, however, indicating that the increased movement was not caused by left ventricular action.

Increased pulsations along the pulmonary arch, not necessarily associated with undue prominence, may direct the attention to the possibility of a thyrotoxicosis or patency of the ductus arteriosus. Expansile pulsations of the pulmonary artery branches indicate a wide pulse pressure in the lesser circulation, these findings do not accompany a relative regurgitation. A stiff-walled aortic vessel may reveal a marked shift in toto.

Measurements attempt to establish standards of normal and thus help to decide whether or not a given case is within the range of normal variation and if not, to give mathematically the degree of deviation from normal. It must be understood that cardiac size and shape within the range of normal variation may well coexist with disturbed function, coronary artery disease and constrictive pericardial disease may be cited as examples. Because of the range of normal variation, no sharp distinction can be drawn between findings in the upper normal range and those in the incipient abnormal stage, and a heart which is originally small may enlarge considerably before it exceeds the upper limit of normal. Also the muscular wall may increase in thickness without producing appreciable alterations in shape and size of the silhouette. The application of average figures is of limited value since we are dealing clinically with one individual, and the use of absolute figures likewise is of little practical use, such figures must be correlated with other characteristics of an individual, introducing coefficients of correlation. Standards derived from people in the best of physical condition are not quite the same as those of the average population. Furthermore, one cannot compare orthodiagraphic with teleroentgenographic standards. The common methods of measurement stress the formal-quantitative side and are insufficient as to the functional-quantitative aspect.

Unless calcification is present, no reliable method of accurately determining the size of the ascending aorta exists. A normal aortic size is compatible with a marked degree of hypertension of long duration.

No determination of heart size short of the actual volumetric reconstruction is correct. The antero-posterior dimension of the heart, the depth, must be considered. The correlation coefficient between heart size and external somatic measurements is too low to have great statistical signifi-

cance The transverse diameter and the cardio-thoracic ratio are poor criteria since they depend too much on body build

Much interest is attached to possible changes in the size of the silhouette as one may observe it in the course of infectious disease, under the influence of therapy and during physical exercise and pregnancy One hears statements that a failing heart has diminished in size as compensation became restored This is possible Often, however, pericardial fluid has been merely resorbed or the position and shape of the heart have changed as the size of the liver decreased One should likewise look with much doubt upon statements that an aneurysm of the aorta became smaller in the course of antisyphilitic therapy And one will commonly find in comparing two films of the same patient, taken at different times, that the criteria for correct comparison are not given It is almost impossible to make a roentgenologic study while exercise is being continued, and following strenuous exercise an identical position of the diaphragm, of the chest and of the cardiac cycle is rarely obtained Because of the marked physiologic changes which take place immediately following exercise, one is not permitted to draw conclusions as to the changes which might have taken place during the exercise Pregnancy carries with it a shift of the center of gravity which results in a change in the body position and therefore in the projection of the heart

Much information is missed when the oblique and lateral views are not used This may be illustrated by a few examples It has already been mentioned that the antero-posterior dimension of the heart is of significance This is especially true in instances of displacement of the heart due to deformity of the chest wall An isolated prominence of the conus arteriosus, the outflow tract of the right ventricle, or an enlargement of the left atrium may be visualized only in an oblique view The anterior view may reveal an enlargement of the heart to the left while the oblique or lateral views indicate which ventricle predominates Small aneurysms of the aorta, an encroachment of an aneurysm on the trachea and esophagus, erosion of the spine due to aneurysm, certain types of calcification in the pericardium, coronary arteries, in the descending thoracic and abdominal aorta, coarctation and right-sided course of the aorta are thus diagnosed

Certain terms like mitral or aortic configuration are somewhat misleading These terms are purely descriptive and do not necessarily indicate that the respective valves are affected Thus we find a straight or convexly prominent middle portion of the left cardiac contour often in association with a poorly visible aortic knob not only in mitral valvular disease but also in the following conditions In the hyposthenic constitutional type, in emphysema, in thyrotoxicosis, in certain congenital or acquired lesions of the pulmonary artery, and in the presence of right convex scoliosis of the spine And we find a prominence of the aortic shadow, a prominence of the left lower contour together with a deepening of the waist of the left contour not only in aortic valvular disease but also in the following conditions In the hypersthenic type, together with a high position of the diaphragm,

among aged individuals, and in many instances of hypertensive and atherosclerotic disease. A pseudo-aortic configuration is represented by the wooden shoe type of heart, as observed with the tetralogy of Fallot.

One often speaks of cardiac dilatation where it would be more correct to say enlargement of the silhouette. This applies to instances of moderate degrees of pericardial effusion of different etiology including myxedema and glomerular-nephritis. The enlargement of the silhouette may also be caused by the thick fibrous layers of adhesive-constrictive pericardial disease. Excessive degrees of hypertrophy without any dilatation, likewise, cause enlargement of the silhouette. Often the roentgen examination will shed no light on the different etiologic factors of cardiac dilatation which may as easily be caused by diphtheria, myxedema, beri-beri, arterio-venous anastomosis or a combined valvular lesion. Neither is it possible to correlate the degree of dilatation with the efficiency of the heart muscle. For this, the determination of the work of the heart as expressed by stroke or minute volume has a higher statistical significance. However, it is of value to determine whether the dilatation predominantly affects the ventricular or the atrial mass. The silhouette of the heart, in an instance of left atrial enlargement of excessive size may fill the chest cavity transversely and yet a fair function of the circulation may be maintained for a long time.

The roentgenological picture of a pericardial effusion of a marked degree is rather characteristic, but it may be rendered quite atypical by localized obliterations of the pericardial cavity. If the superior recessus is affected, the shortening of the vascular shadow to a short pedicle does not result. Obliteration of the pericardial space along the cardiac surface results in subdivisions in the silhouette contours. In both instances, therefore, cardiac enlargement rather than pericardial effusion may be erroneously diagnosed. Old encapsulated right-sided exudate has been confused with an aneurysm of the proximal portion of the aorta because other roentgenological and clinical signs of chronic adhesive pericardial disease had been overlooked.

It is not correct to assume that oblitative, adhesive and constrictive pericardial disease necessarily leads to cardiac dilatation, as a matter of fact one may find a rather small silhouette and the constrictive process may even counteract an enlargement of the left atrium in the presence of mitral disease or of the left ventricle in the presence of aortic valvular disease.

The very first part of the ascending portion of the aorta cannot be visualized (unless its borders are outlined by lime salt deposits) and therefore a fusiform enlargement as well as a small saccular pouch may escape observation. Because of the same invisibility, small pouches which develop from the arch either from its convexity in a cephalic direction between the brachio-cephalic vessels or from its concavity in a caudal direction may be completely missed. Often the aorta of younger individuals, who are affected by a marked degree of aortic valvular regurgitation or by a marked increase in the systolic and diastolic pressure, is found to be dilated. This should be considered as a dynamic dilatation and preferably not diagnosed as

an aortitis or aneurysm. Those rare aneurysms of the ascending aorta which develop forward and to the left are readily confused with lesions of the pulmonary artery, particularly since they give rise to clinical signs and symptoms at the left side of the mid-line. In the differentiation of thoracic aneurysm from other mediastinal masses, the following points are of value. Views from different angles will show whether in some the mass can be definitely shown separate from the aortic shadow and likewise whether in some it is a definite outgrowth from the aortic shadow, in aneurysm the adjacent portions of the aorta will usually show some widening, in aneurysm the chief axis of the mass is determined by two forces, that of gravity and that of the systolic impact, and finally in aneurysm the contours are often lightly outlined in shell-like fashion by lime salts.

•

ROENTGENKYMOGRAPHY ITS CLINICAL AND PHYSIOLOGICAL VALUE IN THE STUDY OF HEART DISEASE *

By WENDELL G SCOTT, A B, M D, and SHERWOOD MOORE, M D,
St Louis, Missouri

UNTIL recently the fluoroscope has been the only clinical means for routinely investigating the functional movements of an organ or structure. Frequently these movements are so small and quick that they cannot be accurately registered by the eye. The crystals of barium-platino-cyanide in the fluoroscopic screen produce a "lag" and "afterglow" which make it impossible to observe accurately fast movements. Furthermore, the only records of such studies are the subjective notes of the observer. Attempts to determine the time occurrence of related movements are very difficult, particularly in roentgenoscopy of the heart. Cinematography is now possible but the procedure is complicated, expensive, and is as yet unsatisfactory for daily use. In 1911 a Polish physiologist, Sabat,¹ adapted the moving slit camera of the physiology laboratory so that it could be used to study the movements of the heart by the roentgen-ray, and thereby inaugurated a new and accurate method for graphically recording functional movements on a single film. Independently of Sabat's work, Gott and Rosenthal² of Munich in 1912 devised a similar apparatus and named its application "Rontgenkymographie." In 1916 A. W. Crane³ compared his kymographic tracings with polygraphic and electrocardiographic waves. Robert Knox⁴ of London in 1922 contributed the next paper on kymography, and in 1925⁵ suggested its application to the investigation of esophageal and gastric peristalsis. Knox, like the others, was handicapped by the lack of sufficient electrical energy for the production of convincing radiograms. These earlier workers employed from one to four slits, which made it possible to record only that number of points on the heart's surface. To Pleikart Stumpf⁶ of Munich belongs the credit for developing the modern kymograph, as it was he who in 1928 introduced the use of a grid with multiple slits sufficient in number to reproduce the general outline of the structure. I. Seth Hirsch⁷ of New York in 1934 introduced Stumpf's work to American roentgenologists and made original contributions of his own, particularly in recording simultaneously the heart sounds, the electrocardiogram and the kymogram.

PRINCIPLES AND TECHNIC OF KYMOGRAPHY

It must be understood that the kymographic method records only movements at certain points on the border of the heart. These points are small,

* Received for publication March 9, 1936. (Originally presented as an exhibit at the meeting of the Southern Medical Association, Nov. 19 to 22, 1935.)

From The Edward Mallinckrodt Institute of Radiology, Washington University School of Medicine, St. Louis, Missouri.

are equally spaced, and correspond to the width of the slit in the grid—namely 0.4 mm. The grid* is a large sheet of lead in which the slits are cut horizontally and it is placed next to the patient's thorax (figure 1)

FIG 1 Diagrammatic sketch of kymograph. In this arrangement the grid is fixed, the film moving downward during the exposure and the kymograms appear as in figure 2. Another method is to move the grid at the time of exposure with the film remaining stationary. (Modified after Stumpf.)

The slits must be sufficiently close together so that on looking through them it is possible to recognize the shape of the organ the movements of which are to be recorded. Generally, slits placed 12 mm apart are suitable. During a single continuous exposure of 1 + second the film is moved downward behind the fixed grid a distance slightly less than the grid spacing—actually 11 mm. This explains the narrow white lines which divide the kymogram into frames and also prevent an overlapping of exposures (figure 2). It is well to emphasize that each frame is a record of the movement of a very small segment of the heart border registered on 11 mm of film.

By this procedure the varying shape of the heart at any instant in its cycle is reproduced on the film. The marginal contour of the heart is recorded in a wave-form, because the movement of the margins is a lateral expanding and a medial contracting thrust. Occurring simultaneously with the marginal movements are changes in the density of the heart shadow corresponding to systole and diastole. They are shown as transverse bands, the better illuminated representing systole and the less illuminated diastole. Parts which do not move are reproduced as straight lines parallel-

* A detailed description of the kymograph is given in references 7, 13, 21, 22

FIG 2 Kymograms of a normal heart

(a) With slits horizontal for registering lateral movement—film moved downward
On the left border in frames 8-14 are the waves of the left ventricle, frames 6-7 left auricle, frame 5 pulmonary artery, 1-3 descending aorta. Over the right border in frames 10-12 are waves of right ventricle, frames 7-9 right auricle with superimposed ventricular waves

(b) With slits vertical to record vertical movement—film moved horizontally
Frame 1 shows right ventricular waves, frame 2 composite left auricular waves, frame 6 aorta, frame 7 pulmonary artery, frame 8 left auricle, frames 9-11 left ventricle

The white horizontal lines which divide kymogram into frames are the unexposed portions of the film. The points on the ribs and diaphragm which overlie a slit appear as step-like shadows. The pulmonary markings are shown as wavy lines. The contour of structures without movement or possessing movement in a direction perpendicular to the slits is recorded as vertical lines. Characteristic waves are seen over the borders of various chambers and great vessels

ing the direction of the movement of the film. The kymogram thus shows the size and outline of a structure and graphically registers the movements of numerous individual points that are evenly distributed over the margins of the structure radiographed.

THE READING OF KYMOGRAMS

The size and shape of the heart or structure radiographed are analyzed in the same manner as are teleroentgenograms. The trough of the wave is that particular point at maximum systole, while the peak of the wave is the same point at maximum diastole. (Figures 2A and 2B.) The lower leg of the wave represents the diastolic phase of the cardiac cycle while the upper leg represents the systolic phase. If all the peaks are connected by one line and all the troughs by another, two outlines are obtained with a space between them which Stumpf^{8,9} has termed the "Movement Space" of the heart. For practical purposes the inner line represents the systolic, the outer the diastolic, size. The character of the "Movement Space" varies with individuals, but remains constant for the same person under the same conditions. It should be stressed that the amplitude of the waves is an accurate measure of the change in cardiac volume only when the heart border is exactly at right angles to the slits and rotates about a central and vertical axis.

TRACINGS OF VENTRICULAR WAVES
PRODUCED BY DIFFERENT TYPES OF MOTION

FIG 3 Tracings of ventricular waves produced by different types of motion

The individual waves show a marked degree of variation. When the movement is rapid the contour of the curve tends to parallel the slit. During slow movement the film travels a definite distance and an oblique line is formed. A cessation of movement is shown on the contour of the waves as a step formation (figure 3). Over the ventricles and great vessels the

waves are asymmetrical. That is, one leg is rectilinear and the other oblique, which means that the movement is quick in one direction and slow in the other (Review figure 2 and figure 3)

Figure 4 illustrates the method of comparing the time occurrence of movements at different points by tracing the various waves on a sheet of

FIG 4 Diagrammatic representation of the time relationships of movements occurring simultaneously in ventricle, auricle, and aorta

The diagram illustrates the method of comparing the time occurrence of movements at different points by tracing the waves on ruled paper. The tracings are begun at the white lines at the lower edge of the various frames. The time correlation is then facilitated by drawing parallel lines.

Notch (a) coincides with the first heart sound, and indentation (b) with the second sound (Hirsch)

ruled paper. The tracings are begun from the white lines at the bottom of the various frames. The time correlation is then facilitated by drawing parallel lines. Thus it is readily appreciated that the straight limbs of the ventricles and great vessels occur at approximately the same time but run in opposite directions. The quick movement of the ventricle is from without inwards, during systole. In the aorta and pulmonary arteries the quick movement is from within outwards due to their sudden filling by ventricular systole. The bend on the diastolic limb of the ventricular wave corresponds to the beginning of auricular systole. Likewise at the time of auricular systole the ventricle has attained only $2/3$ to $3/4$ of its maximum volume. This fact, namely that auricular systole is an important and effective hemodynamic force, confirms the ingenious experiments made by Gesell¹⁰. His extraordinary work was done in Erlanger's laboratory. We are indebted to the latter for many helpful suggestions.

Since the film is moved at a uniform rate of speed, every millimeter which the film travels will correspond to a definite period of time. With this technic the film moves 11 mm during an exposure of 1 second and a distance of 1 mm will then correspond to $1/11$ of a second. In each frame the recording of the waves always begins at the lower edge and ends at the top. Thus by measuring with calipers or a square of ruled glass⁸ the distance from the beginning of the record to any desired point on a wave and marking this same distance in another frame, the time occurrence of the movement in question can be determined (figure 4). The outward movement of the aorta is usually a good starting point for studying the time

and duration of the heart cycle. In the same manner the time required for systole and diastole in a cardiac cycle can be determined.

By simultaneously recording the heart sounds and kymogram⁷ it can be similarly shown that the first sound coincides with a notch on the systolic limb of the ventricular wave. The second sound corresponds to the end of ventricular systole and is registered as an angulation on the retraction wave of the aorta (Figure 4). Lack of space prohibits a further discussion of physiological facts obtained from kymograms.

CLINICAL APPLICATIONS OF KYMOGRAPHY

In cardiology the kymogram offers two sources of information. (1) It identifies the topographical position of the chambers of the heart and great vessels as each part produces characteristic waves. (2) It permits a study of the amplitude, course and time relationships of the various movements in normal and pathological hearts.

In considering the first point, it has been proved^{7,9,11} that in the erect position a majority of normal hearts show pure ventricular movements over the right lower border (figure 2). This area was formerly considered as part of the right auricle. In cases of mitral disease the extent of an enlarged left auricle is recognized by the auricular waves over the upper left heart border. The chambers constituting the posterior cardiac silhouette can be identified and their extent determined by taking a kymogram while the patient is swallowing an opaque meal. In this way the movements of the different chambers are imparted to the esophagus and can be recorded (figure 5).

A second source of information lies in a study of the type of movement recorded. This is best considered under two heads: (A) Changes in the movement as a whole, and (B) Changes in the form of individual waves.

(A) *Changes in the Movement as a Whole*. Stumpf^{9,12,21} has reported that with beginning hypertrophy of the left ventricle there is a widening of the "Movement Space" over the superior half of the ventricle. In left ventricular hypertrophy with myocardial damage the whole "Movement Space" is decreased, especially over the apex. However, there are also normal hearts in adults that have only a small lateral apical thrust. Lack of movement at the apex is a pathological indication only when confirmed by other signs or when the apical movement has changed in the interim between observations.

In diseases of the pericardium there is a marked reduction in the amplitude of movement. The case of adhesive pericarditis reported by Johnson¹³ revealed practically complete absence of motion over the left ventricle and right heart border with diminished aortic and left auricular waves. We include here a case of tuberculous pericarditis with similar findings (Figure 6). In the diagnosis of pleuro-pericardial-diaphragmatic adhesions the kymogram is of considerable value, as is demonstrated in figure 7. There

should be greatly reduced movements in the presence of calcification in the pericardium²¹

Bickenbach¹¹ and von Braunbehrens¹¹ have shown that characteristic changes occur in the movement over areas of cardiac infarction. The zone of infarction is recognized by the absence of motion in several frames,

FIG 5 Oblique kymogram of esophagus made while patient swallows a barium meal for purposes of identifying chambers constituting the posterior cardiac silhouette. Each chamber in the posterior silhouette transmits its characteristic movements to the adjacent portion of the esophagus.

FIG 6 Tuberculous pericarditis. There is complete absence of movement over the left ventricle and lower portion of right heart as shown by the vertical lines in these frames. The auricular and aortic waves are feeble.

A 43-year-old white married foreman who worked in a grinding (sand) factory for 17 years, finally developing a silico-tuberculosis. On admission he was orthopneic, decompensated and critically ill. Heart was greatly enlarged, sounds were extremely faint, blood pressure 130/110, and there was a pulsus alternans. A series of eight pericardial taps was performed, removing a total of 1240 cc of yellow turbid fluid in which acid fast bacilli were demonstrated. Guinea pig inoculation was positive for tuberculosis. Following the first few pericardial paracenteses, air was reinserted, producing a hydropneumopericardium which revealed a thickened pericardium, in places $1\frac{1}{2}$ to 2 cm in thickness.

while there is ample motion in the frames directly above and below. We have observed a case which presented this picture, and the clinical evidence, including the electrocardiograms, conclusively confirmed the diagnosis of cardiac infarct (Figure 8). According to von Braunbehrens,¹⁶ an aneurysm of the ventricular wall gives paradoxical pulsations, i.e. the thin walls of the sac will show an outward movement during the medial contraction of ventricular systole.

In coronary heart disease the amplitude of the ventricular waves is noticeably diminished (figure 9). These observations are of significance only

FIG 7-a

FIG 7-b

FIG 7 Kymogram showing presence of pleuro-pericardial-diaphragmatic adhesions
 (a) Shows absence of movement over right heart border as a result of pleuro-pericardial-diaphragmatic adhesions

(b) Illustrates the presence of movement 13 days after a cardiolysis of the old Brauer type Patient was a 36-year-old white married farmer who developed his first attack of rheumatic fever at the age of seven For past five years he had become progressively more dyspneic on exertion until at time of admission he could scarcely walk At that time he was decompensated and had signs of mitral stenosis and insufficiency with auricular fibrillation complicated by pleuro-pericardial-diaphragmatic adhesions over the right heart border After establishing cardiac compensation by digitalis, Dr Evarts Graham performed the old type Brauer cardiolysis, freeing a dense band of adhesions along the right heart border and sternum Recovery was uneventful and patient left hospital in two weeks greatly improved and can now do light tasks without becoming dyspneic

when associated with a straightening or sagging of the left heart border, as first reported by Levene and coworkers¹⁷

(B) *Changes in the Form of Individual Waves* The kymographic waves show a wide variety of forms even in normal hearts. This is especially true of the ventricular waves. Reports by other workers and a study of our own material have convinced us that at least three variations, and possibly a fourth, in the ventricular waves are characteristic of recognized cardiac disorders.

(1) In the so-called "nervous," "irritable" or "excited" heart disturbances,²¹ a sharp peak appears on the crest of the ventricular wave at the

FIG 8 Infarct in ventricular wall shown in kymogram. The area of infarction is recognized by the absence of motion in frames 1 and 2 with adequate movement on either side.

White married Italian woman 60 years of age. Three weeks prior to admission she experienced a severe precordial pain which persisted. On admission she was cyanotic, orthopneic, and exhibited Cheyne-Stokes respiration. B P 112/70. Heart greatly enlarged. E K G showed auricular fibrillation and evidence of a coronary occlusion. Kymogram made six weeks after coronary accident.

beginning of systole (figure 10) This type of heart is found almost exclusively in individuals of the asthenic habitus

(2) In cases of hyperthyroidism, the waves are abnormally high and the period of systole is extremely short (figure 11) The waves are biconvex

FIG 9 Coronary heart disease There is a flattening of the outline of the left ventricle with a marked diminution in amplitude of the movement The waves are actually of less amplitude than those of the right ventricle

A 65-year-old man who had experienced extremely severe attacks of angina pectoris 2 to 3 times weekly for the past two years EKG showed evidence of myocardial damage Patient died suddenly five weeks later, presumably from a large cardiac thrombosis Post-mortem examination revealed an extreme degree of calcification in the coronary arteries

(3) In aortic insufficiency, there is an immediate and uniform filling of the left ventricle, which is shown as a continuous lateral movement (Figure 12) In advanced cases the amplitude of the waves is greatly increased

FIG 10 "The nervous heart" The additional little peak on the ventricular waves just preceding systole is characteristic of hearts easily excited

Hearts of this type are usually found in individuals of the asthenic habitus White married woman 27 years of age She was excitable, emotional and undernourished

(4) In myxedema, the ventricular waves are low and rounded and appear to be characteristic of this disturbance (figure 13) However, other types of myocardial degeneration may produce similar pictures although we have not seen them

Our study of cases with lesions of the mitral valve has been disappointing as the vibrations and alterations in the hemodynamics produce complex waves which are extremely difficult to analyze. In mitral lesions, the diastolic hmb of the left ventricle frequently appears as a smooth oblique line

FIG 11 Heart in hyperthyroidism. Note the tachycardia, the generally increased amplitude of the waves and the short phase of systole. Ventricular waves are biconvex. Patient is a 50-year-old white male with exophthalmic goiter. Basal metabolic rate was + 56 per cent.

ending in a short plateau which precedes systole¹⁸ (Figure 14). Zdansky and Ellinger¹⁹ report that a characteristic auricular curve is present in mitral stenosis. We have been unable to confirm the consistent appearance of either observation.

The aortic waves exhibit pathognomonic variations in two cardiac dis-

orders, aortic regurgitation and aortic stenosis. In aortic regurgitation there is marked increase in the outward filling of the aorta and a very prompt emptying of the vessel as part of the blood rushes back into the ventricle. The curve is analogous to that of the Corrigan pulse (figure 12). With aortic stenosis the outward thrust becomes an oblique line as the aorta is filled slowly due to the narrowing of the orifice (figure 15). The period of ventricular systole is prolonged.

FIG 12 Aortic insufficiency. There is an immediate and quick filling of the left ventricle as shown by the straight diastolic leg. Ventricular and aortic waves are greatly increased in amplitude. The aortic wave retracts quickly and is analogous to that of the Corrigan pulse.

A 37-year-old white married woman, a known luetic who has been treated for six years. Aortic insufficiency present from time of admission. Five years ago patient developed syphilis of cerebrospinal meninges. B P 135/5. Wassermann test 4+. Heart greatly enlarged.

In aneurysms of the aorta, the amount of movement is variable and decreases with the volume of the blood in the sac, the size of the clot, and the thickness of the sac wall. Practically all aneurysms show movement, either intrinsic or transmitted. Kymograms of aneurysms of the ascending aorta reveal waves that are symmetrical, i.e., both the outward and the contracting forces are of the same type and produce a pyramidal-shaped wave.

(Figure 16 and figure 17) Kymography is an aid in differentiating aneurysms from mediastinal tumors because not all mediastinal tumors exhibit movement. Furthermore, although many tumors may exhibit movement, it will not necessarily be aortic in origin. The pulmonary arteries or

FIG 13 "The myxedema heart" The ventricular waves are low, slow moving, and have a small peak preceding systole

A 36-year-old colored woman who has been observed in the Out-Patient Department for two years. Her BMR has never been above — 20 per cent even following thyroid medication. B P 115/75. EKG showed evidence of myocardial damage.

ventricles may be responsible for transmitting the motion, and it will then bear pulmonic or ventricular waves. The kymograph can thus be of aid in diagnosing mediastinal tumors but cannot make the differentiation in all cases.

In our experience even early luetic aortitis produces a surprisingly characteristic kymogram (figure 18) The waves over the ascending aorta are prominent, increased in amplitude, retract slowly and simulate those of aneurysms The aortic waves on the descending aorta are unchanged In

FIG 14 Mitral stenosis and insufficiency In this case the waves are feeble and poorly defined, which are an indication of weakened musculature Patient was decompensated and had auricular fibrillation Note the truncated waves over lower heart border White male, aged 52, with history of rheumatic heart disease of 12 years' duration B P 105/70 (Courtesy Dr C Malone Stroud)

luetic aortitis there is a destruction of the elastic fibers in the media and a consequent loss of tone of the aortic wall which permits it to expand promptly and contract slowly This may allow a differentiation from arteriosclerotic changes

In hearts with hypertension the kymogram reveals no distinctive record

The amplitude of the aortic waves may be diminished, while those of the ventricle are increased (figure 19). Similar findings occur in arteriosclerotic heart disease and the aortic waves may be of average amplitude even in the presence of extensive calcification.

FIG 15 Aortic stenosis. Note that the normal horizontal line of aortic filling has become oblique, indicating a longer period of filling. Corresponding to this change is the prolonged phase of ventricular systole.

A 48-year-old white man who has had rheumatic heart disease for past 20 years. Signs of mitral stenosis and aortic stenosis present for past three years. B P 140/90.

Brednow and Deppe²⁰ in an excellent paper describe the changes produced in the kymogram with various arrhythmias. As yet we have been unable to study this problem but hope to do so in the near future.

Alterations in auricular waves are frequently seen on kymograms, but

their records are vague and usually complicated by the superimposed ventricular thrust. Until there is further improvement in the technic of reading and of making kymograms the auricular waves will remain difficult to interpret.

FIG 16 Aneurysm of ascending portion of aorta. Here the aortic waves are symmetrical, pyramidal in shape, and greatly increased in amplitude over ascending portion of arch. Aortic waves over descending aorta are not altered.

Colored man 45 years of age. Known luetic since 1932 with 4+ Wassermann test. B P 200/115.

The changes in the heart muscle which can be interpreted from the electrocardiogram as indicative of myocardial damage should presumably produce variations in the movements of the heart muscle which can be recorded on the kymogram. As yet we have been unable to identify clearly

specific changes, but feel that this problem offers a promising field for future investigation

SUMMARY AND CONCLUSIONS

1 Roentgenkymography permits a purely objective and accurate recording of the physiological movement displayed by an organ or structure

2 The procedure requires relatively simple and inexpensive apparatus. The cost of a kymogram is the same as that of the regular chest film

FIG 17 Aneurysm of descending portion of aorta. Even in the presence of calcification in the clot typical aortic waves are seen over borders of aneurysm. A 51-year-old colored man. Known luetic for 30 years. B P 136/76

3 The kymographic film is a permanent record which may be studied at leisure and compared with other records from time to time, as during the course of a disease

4 Kymography is an effort to fill the gap between roentgenoscopy and roentgenography and is not an attempt to replace either

5 Kymographic waves are the records of the form, amplitude, direction,

speed, frequency, and time relationships of movements occurring at equally spaced points on the border of an organ

6 The kymogram, as does the teleroentgenogram, portrays the size and outline of the heart, and in addition provides a record of the movement of

FIG 18 Luetic aortitis The waves over ascending aorta are prominent, increased in amplitude, and retract quickly These changes permit a differentiation between luetic aortitis and arteriosclerotic lesions

A 48-year-old colored widow who complained of precordial pain and palpitation of one year's duration B P 138/98 Faint systolic murmur heard over aortic area Wassermann test 4 +

the chambers of the heart, and information so obtained is frequently of clinical value

7 It permits a topographical identification of the heart chambers and great vessels

8 There are diagnostic kymographic tracings in certain types of heart disease, notably in aortic insufficiency, aortic stenosis, hyperthyroidism, myxedema, constrictive adhesive pericarditis, tuberculous pericarditis, pleuro-

pericardial-diaphragmatic adhesions, aneurysms of the ascending aorta, luetic aortitis, cardiac infarction, "nervous" or "irritable" hearts. With future research and the accumulation of data, the characteristics of other types of heart disease may be identified.

FIG 19 Essential hypertension. Note aortic waves are inconspicuous and ventricular waves of average amplitude.
Patient a young man 29 years of age with essential hypertension. B P remains constantly close to 220/110. No cardiac enlargement.

9 Kymography frequently proves of value in the differentiation of aneurysms and mediastinal tumors

10 The fund of information already gained on the physiology of movement has firmly established kymography as an important method in research

11 Kymography has been applied to the study of many structures exhibiting movement The results of our work in this field will be published shortly

The authors are indebted to Dr David P Barr, Dr Arthur Strauss, and Dr Hiram Liggett of the Department of Medicine, and to Dr Everts Graham and Dr J J Singer of the Surgical Department for permitting study of patients on their services Without their cooperation this work would not have been possible

REVIVAL OF HUMAN HEARTS *

By WILLIAM B KOUNTZ, *St Louis, Missouri*

ATTEMPTS to develop a method which would make possible studies on the revived human heart have been made during the past six years. A number of references to such work may be found in the literature. The chief object of most of the observers has been to determine the viability of the organs, and the material has, with few exceptions,^{1,2} never been utilized for physiological study.

There are two excellent reasons why observations on the function of organs taken from the human body after death are of importance. One is that by this means the individual characteristics of the organs of man may be established. The span of life and the rate of physical development of man suggest that there is a basic difference between his organs and those of the usual laboratory animal, upon which most of the physiological observations are made. Again, it is a well known fact that characteristics of function differ to some degree in various species of animals. The differences in anatomical structure of the human body and those of laboratory animals may often lead to misinterpretation of results obtained in the physiological laboratory. A notable example of this is the work of Sir Thomas Lewis,³ who studied the nature of bundle branch block and localization of extrasystoles on the hearts of dogs. Because of the differences in anatomical structure of the mediastinum of the dog compared with that of man, Lewis's results were opposite to that obtained later in the human heart. The misinterpretation which resulted from the anatomical differences in the two animals led to a mistaken translation of the electrocardiogram for a period of 15 years.

A second reason that observations should be made on the function of organs taken from the human body after death is that many diseases which are not recognized by anatomical study may be understood. Man lives under circumstances entirely different from those surrounding most animals, which makes it impossible to reproduce the pathological lesions observed in man experimentally. The advent of biochemical studies in medicine has made possible the analysis of perfusing solutions, and thereby the study of functional pathology in far greater detail than heretofore. By such methods our knowledge of the relationship of individual organs to disease may be developed.

A technic for the revival of the human heart had first to be developed. The method of perfusion of the heart has not advanced since the days of Langdorff, who isolated a heart, inserted a cannula into the aorta, and per-

* Read before the American College of Physicians, Detroit, March 4, 1936.

From the Department of Medicine, Washington University School of Medicine, and the Barnes Hospital, St Louis, Missouri.

FIG 1 The outline drawing of the apparatus used for the work shows the Starling heart-lung apparatus with its arterial pressure unit. The gravity pressure reservoir which was attached to the cannulae in the ventricle and the pressure valve and coronary artery reservoir which was attached to the cannulae in the coronary artery system are present on the left of the drawing. A method for recording the size of the lungs, the volume of blood, and the rate of blood flow is noted. A respiratory pump to connect with the lungs is presented in the left hand corner of the drawing. Mercury manometers which record the perfusion pressures are attached to the perfusion systems.

fused the coronary vessels by backflow of the perfusing solution through the aorta. This method was satisfactory as a means of determining the viability of the heart but would not suffice to keep hearts viable for a period sufficiently long to permit physiological observation. Some exceptions to this were noted in the hearts of children. In general the hearts were found to dilate in a short period if the pressure in the aorta was raised sufficiently to permit perfusion of the coronary system. If low pressures were maintained the hearts revived imperfectly or not at all. For significant results a new method of perfusion was required. It was necessary to maintain a ventricular pressure in order to stretch the heart and permit it to contract. It was necessary also to perfuse the coronary artery at a pressure much higher than the ventricular muscle could withstand.

A cannula was constructed which would permit the development of different pressures in the ventricle and in the coronary arteries. Cannulae were inserted into the coronary arteries through the aorta. A large cannula was then introduced over the coronary ones through the aorta and past the aortic valves. Different pressures were maintained in the two systems by individual reservoirs.

The pressure in the cannulae of the coronary arteries was maintained at about 120 mm of mercury, whereas that in the ventricle was varied according to the contractility of the heart. By this method one could perfuse the hearts for a considerable period or could make heart-lung preparations which would last for several hours.

The hearts of 127 individuals who had died of various conditions have been studied. Sixty-five have been revived to the point of ventricular contraction. Of the 65, 48 developed regular cardiac mechanism and beat for a period of at least two hours. Fifteen heart lung preparations have been made and cardiac contractions against a blood pressure of 120 mm of mercury have been maintained for as long as four hours. The functions of the other hearts were studied by perfusion of the coronary vessels.

The time after death and the nature of the disease had definite influence upon the viability of the heart. It is a universal rule that the sooner the heart is obtained the more readily it revives. This is particularly true in individuals dying in good health and with heart disease. It is not so true of people with chronic illness. Since time after death was an important factor in revival, effort was always made to obtain the body as soon as possible. The actual time limit varied, however, from five minutes to six hours.

The causes of death were also varied and ranged from heart disease to death by accident. The age of individuals varied from still birth to an adult of 73. In general it could be said that in those cases dying from chronic illness revival could as a rule be accomplished more easily than in those succumbing to acute infection. The hearts of individuals who died of tuberculosis revived more easily than those of any other group whose death was due to a single cause. This applied not only to tuberculosis of

the lungs but also to generalized tuberculosis. The hearts of children were usually more responsive than those of adults. The greatest difficulty was encountered in the hearts of those who had succumbed to diseases of the heart itself. One exception to this rule was noted. Congenitally defective hearts in our experience were relatively easy to revive. Since the same result was observed in one case of emphysema in which chronic anoxemia had been a pronounced factor, it was thought that possibly decrease in

FIG 2 A chart which demonstrates the viability of hearts in 127 cases. The hearts of individuals dying of heart diseases are the least viable of all patients studied. Time after death is an important factor in reviving the hearts.

oxygen tension of the blood over a long period of time might be a circumstance favorable to revival. In general it was found that the longer the period after death the greater likelihood there was of thrombosis in blood vessels and the greater the probability of dilatation of the heart when the experiment was started.

A large number of problems has been studied in these hearts. The first consideration was the nature of bundle branch block. After the heart had been revived small incisions were made in the skin of the forearms and

left thigh through which small copper electrodes were introduced into the muscles of the extremities. The electrocardiograph was then attached to the body by the usual three leads and a normal record taken. The right or the left bundle branch was then cut and electrocardiographic tracings again made.

Section of the right bundle resulted in a curve which was not uniform in all experiments. The QRS complex was definitely prolonged to as much as 0.24 second. The initial deflection was down in Lead I and up in Lead III. In one instance we obtained a rather high deflection in Lead II, followed by inversion of the complex and T-wave. The character of the complex was varied by contact of the ventricle. Atypical curves were sometimes obtained when the heart was in an abnormal position or the contact to the body was through the left ventricle only.

When the left bundle was cut with the heart in normal position, curves were obtained in which the initial ventricular deflection was up in Lead I and down in Lead III. The curves were usually inverted in Lead II.

In addition to cutting the bundles the surface of the heart was electrically stimulated, and the localization and nature of extrasystoles determined.

Four general types of extrasystoles were observed. Concordant extrasystoles in which the initial ventricular deflection was upright in all three leads were obtained from stimulation of the conus of the right ventricle. Concordant extrasystoles in which the initial ventricular deflection was down in all three leads were obtained from stimulation of the region of the apex of the left ventricle. Discordant curves in which the initial ventricular deflection was up in Lead I and down in Lead III were obtained by stimulating the right ventricle everywhere except at the conus. Discordant curves in which the initial ventricular deflection was down in Lead I and up in Lead III were obtained from the left ventricle, except at the apex which covers a relatively greater area posteriorly than it does anteriorly. These results have substantiated the conclusions of Baker,⁴ whose observations were made on the human heart, and have been directly opposed to observations of Lewis on the dog's heart.

The nervous regulation of the heart was studied in subjects whose bodies were obtained immediately after death. The vagus and sympathetic nerves were isolated in the neck and stimulated by an electrical current. The results indicate that the action of the vagus and sympathetic nerves with a heart in normal mechanism was different from that previously supposed as far as the coronary flow was concerned. The vagus nerve when stimulated caused an increase in the coronary flow in these hearts instead of a decreased flow, as in the dog. The sympathetic nerve when stimulated decreased the flow through the coronary arteries in the experimental heart of man.

The coronary flow in the perfused beating heart and in the heart lung preparations made from the heart and lungs of these individuals is under consideration at the present time. The action of drugs which are com-

FIG 3 Drawing of a heart opened through the left ventricle showing an incision passing through the left bundle branch which produced curves resembling the common type of bundle branch block.

monly used in clinical medicine in the treatment of heart disease, and of others which are known to have a specific action, were studied by injecting them into the blood perfusing the coronary system of normal hearts. The hearts were then caused to dilate by cutting off the blood supply. After maximum dilatation of the heart was produced perfusion was started. It was found that the action of drugs was not the same in different states of diastolic volume of the heart. As a rule the drugs which decreased the coronary flow in the normal heart often increased the flow when the heart was dilated. The observation suggests that no single coronary dilator can be expected to act as such under all conditions. It emphasizes the clinical importance of studying the heart before a drug is given.

SUMMARY

A method is presented for revival of the human heart after death. This we believe establishes the possibility and the practicability of such a procedure. The results obtained from the study of the revived human heart indicate that information which may not be obtained from any other source is available from this procedure. We suggest that development of a branch of physiology and pathology based upon direct studies of isolated human organs would give us a far greater knowledge of deranged functions of organs in disease. It also might enable us to determine the basic physiology of many units of the body of which at present we know but little.

LYMPHOSARCOMA AND HODGKIN'S DISEASE · CLINICAL CHARACTERISTICS '

By SOLOMON GINSBURG, M D , *New York, N Y*

A COMPREHENSIVE survey of the available data reveals the following outstanding clinical characteristics of Hodgkin's disease

1 *Malignant and Protean Character of Hodgkin's Disease* Hodgkin's disease is a specific malignant disease which most frequently first manifests itself clinically by enlargement of the lymph glands and spleen accompanied by toxemia, anemia, wasting and cachexia. However, it is not confined to these lymphoid organs only. It is of historic interest to record that it was Hodgkin himself who was the first to make this observation, which has been repeatedly corroborated by numerous students of this disease. Indeed, more than half a century ago, in 1879, Gowers¹ in his comprehensive study of Hodgkin's disease gave details concerning the lesions not only in the lymph glands and spleen, but also in the skin, intermuscular tissues, bones, brain, soft palate, pharynx, tonsils, esophagus, stomach, small intestines, large intestine, liver, pancreas, peritoneum, thyroid, thymus, trachea, lungs, pleura, diaphragm, pericardium, heart muscle, suprarenals, kidneys, testes and ovaries. Further observations by numerous investigators have revealed that not a single organ or tissue has escaped invasion in Hodgkin's disease.

2 *Primary or Predominant Localizations of Hodgkin's Disease in Extra-Glandular Tissues* Hodgkin's disease is rarely, if ever, a uni-local or multi-local lymph-glandular disease. It is almost invariably a widely disseminated and protean disease showing marked variation not only in the duration, character and acuteness of its clinical course, but also in its predominant localization in different regions, tissues and organs in different individuals. Although, most frequently, enlarged lymph glands are the first lesion to attract clinical attention, numerous reports have appeared in the literature in which the primary or predominant clinical localizations of Hodgkin's disease appeared in the adrenals, appendix,³ bladder,⁴ bones,^{3, 4, 5, 6} bone marrow,⁸ brain,⁹ breast,¹⁰ bronchus, spinal cord, esophagus, eye, heart, intestines, kidneys, larynx, liver, lungs, nose, pancreas, peritoneum, pharynx, pituitary, pleura, prostate, salivary glands, skin, spleen, stomach, thymus, thyroid, tongue, tonsil, ureter and uterus.

3 *Presence of Toxemia in Hodgkin's Disease* Toxemia is an invariable accompaniment of Hodgkin's disease. As pointed out in a previous study,¹¹ specific hyperplasia of the reticulo-endothelial elements with or without lymphoid hyperplasia is only one phase and one stage in the pathology of Hodgkin's disease. There are now on record a great number of cases of

* Received for publication October 2, 1935

From the Radiotherapy Department and the Surgical Division, Cancer Service, Montefiore Hospital, New York, N Y

this disease which ran an acute febrile course with toxic symptoms and then terminated fatally in from several weeks to several months. In these cases the fatal issue was caused primarily not by proliferative compressive phenomena, but by a severe toxemia which presented all the characteristics of an acute infectious disease. Although in the chronic forms, the toxic element does not always appear strikingly in the foreground, its unmistakable presence is clearly evidenced in the frequency of the recurring attacks of pyrexia, the progressive anemia and cachexia, the frequently demonstrable foci of necrosis in the specific lesions of the disease and in the parenchymatous degeneration of vital organs in which the specific lesions are absent.

4 *Lack of Pathognomonic Clinical Signs of Hodgkin's Disease* There are no characteristic or positively diagnostic clinical signs of Hodgkin's disease. Neither the character of the glandular enlargement, the blood picture, nor the temperature curve, singly or in combination, provides a conclusively diagnostic picture of Hodgkin's disease. A positive diagnosis can be made only on the basis of microscopic study*. This is easily accomplished by biopsy in accessible regions. The protean character of Hodgkin's disease and its primary clinical localization in internal organs and tissues in many cases may cause it to simulate a variety of local or systemic disorders and to present great difficulty in diagnosis. A biopsy may be unobtainable.

5 *Importance of Radiotherapeutic Diagnostic Test* In the absence of any biopsy there is one diagnostic test, however, which is considered exceedingly important to emphasize, namely, the radiotherapeutic diagnostic test. Since the appearance of the original articles of Pusey and Heinecke, the exceeding radiosensitiveness of both pathologic and normal lymphoid tissues to radium and roentgen-rays has become well known to all students of radiotherapy. The knowledge of this fact has at times been utilized by radiologists to determine whether a given tumor by its ready response to a given dose of radiation is of lymphatic constitution or origin. In Hodgkin's disease, before extensive fibrosis has occurred, the radiotherapeutic test can be of great help in causing a rapid and decided disappearance or diminution of the symptoms and objective signs of the disease.

6 *Unknown Etiology and Lack of Specific Therapy of Hodgkin's Disease* More than a century after Hodgkin's first description of the disease, its etiology still remains obscure, and a specific form of treatment has not been discovered. Chemotherapy and surgical intervention—with rare exceptions—have proved disappointing either as curative or palliative measures. The most efficient local treatment for Hodgkin's disease is universally recognized today to be the radium and the roentgen-ray treatment. The effect of both of these forms of radiant energy is prompt and efficient in influencing the cellular proliferative manifestations of this disease. Even bulky growths and infiltrations have been noted to disappear or regress promptly under radiotherapy, with great symptomatic relief not only of the compressive phenomena but also of the accompanying toxemia.

* Gordon's⁴³ biologic diagnostic test needs further study and confirmation.

7 Unfavorable Prognosis of Hodgkin's Disease Unfortunately, in spite of great improvement in radiotherapeutic technic, permanent cures have not been reported and, although prolongation of life for months and years has been noted by a number of observers, the fatal outcome has not been averted^{24, 25}

Similarity of Lymphosarcoma and Hodgkin's Disease The malignant characteristics of Hodgkin's disease and its close similarity to, if not identity with, lymphosarcoma have been repeatedly impressed upon me ever since I became interested in this problem many years ago. With the passing of the years the more closely and carefully I studied the literature and the personally observed cases the more firmly I became convinced that not only biologically but also clinically the two diseases in their course and manifestations are closely similar, if not identical. Whatever differences are observed at times may be regarded as mere variations of the same disease, which one would expect to encounter in different individuals with different tissue and organ susceptibility and resistance. It is this impression, which gradually has acquired the force of a conviction, that has induced me to review critically the recent literature and a series of 30 cases each of lymphosarcoma and Hodgkin's disease observed at Montefiore Hospital during the years 1922 to 1932.

CLINICAL CHARACTERISTICS OF LYMPHOSARCOMA AND HODGKIN'S DISEASE

Age In both groups of our series the greatest incidence occurred in persons past middle life, as occurs in epithelial cancerous growths. No striking differences were encountered in the age distribution between Hodgkin's disease and lymphosarcoma, as has been claimed by Kundrat and others. The youngest individual in our series was 11 years old. However, there are many reports in the literature of cases of lymphosarcoma and of Hodgkin's disease in children below 10 years of age. The important lesson to bear in mind is that both diseases are encountered most frequently during adult life but may occur at any age.

Sex In his original paper on lymphosarcoma Kundrat²⁶ stated that lymphosarcoma attacks males twice as frequently as females while Hodgkin's disease affects more frequently females. This statement, as was previously pointed out in a recent study, is not confirmed by the experience of other observers. In our series of cases of lymphosarcoma there were 13 females to 17 males, while in the Hodgkin's group there were as many males as females. Hence, whatever the ratio of sex incidence in a particular series of cases might be, it is of little or no significance in making a differential diagnosis between lymphosarcoma and Hodgkin's disease.

Organs and Tissues Involved in Lymphosarcoma and Hodgkin's Disease In our series the following tissues were found involved

Lymphosarcoma

Lymph glands, skin, subcutaneous tissues, muscle, breast, bones, dura, brain, pituitary, parotid, tongue, pharynx, tonsils, larynx, trachea, pleura, lungs, thyroid, thymus, vena cava, aorta, pericardium, heart muscle, stomach, spleen, liver, pancreas, jejunum, ileum, cecum, appendix, rectum, peritoneum, mesentery and omentum, adrenals, kidneys, ureters, prostate, bladder, seminal vesicles, spermatic cord, uterus, vagina

Hodgkin's Disease

Lymph glands, skin, subcutaneous tissues, breast, bones, dura, brain, pituitary, parotid, pharynx, bronchi, lungs, pleura, thyroid, vena cava, aorta, pericardium, heart muscle, thoracic duct, stomach, spleen, liver, pancreas, duodenum, jejunum, adrenals, kidneys, ovaries, uterus, bladder, vagina

A mere glance at the two lists reveals many more organs and tissues involved in lymphosarcoma than in Hodgkin's disease in the present series. To generalize from this series alone that lymphosarcoma has a tendency towards greater systemic dissemination than Hodgkin's disease is hardly warranted. If we but compare Kundrat's famous series of 50 cases of lymphosarcoma with Gowers' parallel series of 50 cases of Hodgkin's disease we shall detect but few differences.

Kundrat's 50 Cases of Lymphosarcoma

Lymph glands, skin, subcutaneous tissues, muscles, breasts, bones, dura, tongue, palate, pharynx, tonsils, larynx, trachea, bronchi, lungs, pleura, thyroid, thymus, pericardium, vena cava, esophagus, stomach, duodenum, jejunum, ileum, cecum, rectum, peritoneum, mesentery and omentum

Gowers' 50 Cases of Hodgkin's Disease

Lymph glands, skin, intermuscular tissues, bones, brain, soft palate, pharynx, tonsils, esophagus, stomach, small intestines, liver, pancreas, peritoneum, thyroid, thymus, trachea, lungs, pleura, diaphragm, pericardium, heart muscle, suprarenals, kidneys, testes and ovaries

However, neither in lymphosarcoma nor in Hodgkin's disease is the pathologic process limited to the organs and tissues enumerated above. In a previous study it was pointed out that it was repeatedly and conclusively demonstrated that not a single organ or tissue had escaped invasion in Hodgkin's disease. A comprehensive survey of the literature and our own observations have revealed that the same holds true for lymphosarcoma. Both diseases are protean in their manifestations. Clinically, both reveal the same marked variation in duration, character, course and selective localization in different regions, tissues and organs in different individuals. In lymphosarcoma as in Hodgkin's disease it is unquestionably true that in large series of cases the invasion of lymph glands is the first to attract clinical attention. Nevertheless, numerous reports have appeared in the literature in which the primary and predominant extra-glandular localization of lymphosarcoma occurred in the following organs and tissues: adrenal, antrum, appendix, bladder, bone, breast, brain (figure 1), spinal cord, esophagus, eye, heart, hemopoietic system, small intestines,^{28, 29, 30} large intestines,^{31, 32} lach-

lymphatic glands, larynx and trachea, liver, lung,^{33, 34} mastoid, mesentery and peritoneum, nasopharynx, neck and pharynx,³⁵ ovary, pancreas, pituitary,³⁶ prostate,³⁷ salivary glands, scrotum, skin,³⁸ spleen, stomach,³⁹ testes, thymus,⁴⁰ thyroid,⁴¹ tongue, tonsil,⁴² and vulva

The recognition that lymphosarcoma and Hodgkin's disease are protean in their manifestation and invade primarily and predominantly not only the lymph glands and spleen but also extra-glandular organs and tissues in different individuals, is of vast clinical importance. It stresses the need to remember that they masquerade under the semblance of a variety of non-malignant as well as malignant conditions, proper differentiation from

FIG 1 (Case 1) Lymphosarcoma or Hodgkin's disease of the brain (Courtesy of Dr C Davison, Neuropathologist, Montefiore Hospital)

which is of great importance from a diagnostic, therapeutic and prognostic standpoint. An early correct diagnosis of lymphosarcoma or of Hodgkin's disease is of vital importance, for in their early proliferative hyperplastic stage the lesions are more circumscribed and are highly sensitive to radium and roentgen therapy—the most efficient local therapeutic agents at our command today. In the later stages radiotherapy may fail because lymphosarcoma and Hodgkin's disease, even if checked in their further course, may have already produced irremediable damage either by marked invasion, compression or toxic degeneration of vital organs like the brain and cord, heart and lungs, liver or kidneys, or by ulceration and perforation of hollow viscera with secondary infection.

Compression Phenomena in Lymphosarcoma and Hodgkin's Disease

A review of the literature and personal observations have impressed me with the fact that invasive growth by direct extension or lymphatic permeation, and lymphogenous and hematogenous metastases play a more important rôle in the fatal issue of lymphosarcoma and of Hodgkin's disease than mere mechanical compression. Nevertheless, the presence and importance of compression in the advanced stages of the disease must be duly stressed. In our series of cases the involvement of organs by compression is shown below

<i>Lymphosarcoma</i>		<i>Hodgkin's Disease</i>	
1 Brain and cranial nerves	2 cases	1 Brain and cranial nerves	2 cases
2 Cord and nerve roots	3 cases	2 Cord	6 cases
3 Trachea	2 cases	3 Trachea	3 cases
4 Thoracic duct	1 case	4 Bronchi	1 case
5 Vena cava	1 case	5 Esophagus	4 cases
6 Ureters	3 cases	6 Left cervical sympathetic	1 case
		7 Thoracic duct	1 case
		8 Vena cava	1 case
		9 Intrathoracic veins	2 cases
		10 Aorta	1 case
		11 Heart	1 case
		12 Cystic and common duct	1 case
		13 Left renal vessels	1 case

While no sweeping deductions can be made from this small series of cases as to the relative frequency of compression in lymphosarcoma and Hodgkin's disease, nevertheless the observation that in the Hodgkin's group compression occurred twice as frequently as in the lymphosarcoma cases deserves attention.

Toxæmia in Lymphosarcoma and Hodgkin's Disease The following toxic or constitutional manifestations occurred in both groups of cases: weakness, anorexia, loss of weight, emaciation, brownish discoloration of skin, anemia, headache and fever. Marked febrile reaction occurred more frequently in the Hodgkin's group than in the lymphosarcoma cases. The Murchison-Pel-Ebstein relapsing type of fever occurred in only one of our entire group of 60 cases, a patient with Hodgkin's disease in the terminal stages. Evidence of necrotization of the lesions with secondary infection was frequently present in both series of cases but seemed to be more pronounced in the Hodgkin's group.

Is the cause of the febrile reaction—frequently more marked in Hodgkin's disease than in lymphosarcoma—due merely to cell necrotization with or without non-specific secondary infection, as believed by some students of this problem, or to be attributed to the presence of a filtrable virus as believed by Gordon,⁴³ Pullinger and others? A definite answer to these questions cannot be given in the present stage of our knowledge. Neither the tubercle bacillus—the most frequently incriminated organism—nor any other known

microorganism has been conclusively proved thus far to be the etiologic agent of lymphosarcoma or Hodgkin's disease

Relation of Tuberculosis to Lymphosarcoma and Hodgkin's Disease

The frequent presence of tuberculosis in Hodgkin's disease and its rarity in lymphosarcoma have been stressed by a number of observers. In our present series of cases pulmonary tuberculosis was found in two of our 30 cases of lymphosarcoma and in four cases of the Hodgkin's group. In the former the lesions consisted of a single calcified nodule in the right lung in one case and of active pulmonary tuberculosis in the other. In the four cases of Hodgkin's disease the findings were as follows: in case 1 the pulmonary lesions were healing and partially healed, in case 2 there was a healed tuberculous lesion in the right upper lobe, in case 3 there was a healed lesion in the right apex, in case 4—one of abdominal Hodgkin's disease with lumbar cord compression and no intrathoracic invasion—disseminated miliary tubercles were found in the lungs, liver and kidneys.

An analysis of the incidence of the type and extent of pulmonary tuberculosis in our group of cases of lymphosarcoma and Hodgkin's disease does not favor a tubercular etiology. Parenthetically, it is worthy of record that only six cases of pulmonary tuberculosis were found in this group of 60 cases of lymphosarcoma and Hodgkin's disease, encountered at Montefiore Hospital during the years 1922 to 1932, during which period nearly 4,000 cases of active pulmonary tuberculosis were observed clinically in this hospital and more than 600 studied at autopsy.

The Blood Picture in Lymphosarcoma and Hodgkin's Disease The presence of a diagnostic blood picture in Hodgkin's disease—secondary anemia, increased number of platelets, leukocytosis, increased number of polynuclear neutrophils, monocytosis, eosinophilia, and lymphopenia, has been stressed by a number of observers. Our own studies at Montefiore Hospital in the present group of cases did not reveal any essential difference between lymphosarcoma and Hodgkin's disease. A marked eosinophilia as high as 60 per cent was encountered in only one of our cases. The case, however, was diagnosed lymphosarcoma by several pathologists, and as Hodgkin's sarcoma and not lymphogranuloma by Dr. James Ewing. Hematologic study of our group of cases would therefore lead one to agree with the large group of observers who have failed to find a uniform diagnostic blood picture of Hodgkin's disease.

Course and Prognosis in Lymphosarcoma and Hodgkin's Disease The malignant character of lymphosarcoma and Hodgkin's disease has been recognized early in the course of their study. However, the impression still seems to prevail that Hodgkin's disease carries a better prognosis than lymphosarcoma. This is true to a very limited extent. Even if we omit from consideration the many acute cases of Hodgkin's disease reported in the literature in which fatal termination occurred within a few weeks or months from the time of clinical onset, a comparison of large series of cases shows that lymphosarcoma and Hodgkin's disease run a closely parallel race.

to the usual fatal issue. The average duration of either is between two and three years, although in either case at times extreme variations of from a few days to more than 20 years have been recorded (tables 1 and 2). The shortest duration of life in our Hodgkin's group was 2 months, the longest, 7½ years, the average, 2 years and 7 months. In the lymphosarcoma group the shortest duration of life was 6 months, the longest duration, 7 years, the average, 2 years and 1 month.

Mode of Death in Lymphosarcoma and Hodgkin's Disease In the past too much stress has been placed on the glandular invasion and enlargement and secondary compression in both lymphosarcoma and Hodgkin's disease, while the widespread invasion of the visceral organs either by direct extension from invaded lymph glands or by lymphogenous and hematogenous metastases has received insufficient emphasis. Moreover, in lymphosarcoma

TABLE I
Prognosis in Hodgkin's Disease

Author	No of Cases	Shortest Survival	Longest Survival	Average Survival	Remarks
1 Ziegler	70	1 month		1-2 yrs	50 per cent dead at the end of one year
2 Hodling and Brown	18	8 months	5 yrs		Treated by x-ray, radium, Coley's toxin
3 Wallhauser		2 weeks	6 "	2 "	Vast literature and personal observations
4 Coley	21	—	7 "		Only one 7-year survival
5 Billich	31	-1 year	7 "	2 3 "

24 Warthin	232		17 "	2-5 "	23 patients well 6 yrs or over
25 Coley		-1 "	22 "		

the toxic factor in the evolution and termination of the disease has been greatly underestimated. In our series of cases, although, as pointed out above, compression was present in 12 of the lymphosarcoma cases and in 25 of the Hodgkin's group, local compression played a predominant rôle in the immediate fatal issue in only 11 of the Hodgkin's cases and in 9 of the lymphosarcoma group. Toxemia and multiple visceral invasions were the most frequent cause of death in both diseases. Terminal pneumonia was a frequent ending.

MODE OF DEATH IN LYMPHOSARCOMA AND HODGKIN'S DISEASE

<i>Lymphosarcoma</i>		<i>Hodgkin's Disease</i>	
1 Tracheal compression	1 case	1 Tracheal compression	1 case
2 Esophageal compression	1 case	2 Compression of stomach, liver and bile ducts	1 case
3 Mediastinal compression	4 cases	3 Mediastinal compression	8 cases
4 Intestinal obstruction	1 case	4 Ureteral obstruction	1 case
5 Cord compression	2 cases	5 Cord compression	1 case
6 Toxemia and visceral invasion	19 cases	6 Toxemia and visceral invasion	18 cases

Differential Diagnosis of Lymphosarcoma and Hodgkin's Disease In a previous study on "Lymphosarcoma and Hodgkin's Disease: Biologic Characteristics" it was shown that none of the biologic diagnostic criteria described by Kundrat to differentiate lymphosarcoma from Hodgkin's disease have stood the test of careful investigation. The present clinical study further corroborates the same conclusion. Indeed, the more one studies this problem the more one becomes impressed that not only biologically but also clinically the two diseases are identical in their malignant manifestations*. Everyone with wide clinical experience with these two diseases knows how extremely difficult, if not impossible, it is to differentiate lymphosarcoma from Hodgkin's disease on mere clinical grounds in the absence of microscopic evidence. I have witnessed many instances in which expert clinicians and radiologists were unable to differentiate one from the other in the clinically most important group of cases—the mediastinal type—in which the aid of the roentgenologist is usually of great value not only from a diagnostic but also from a therapeutic standpoint in guiding proper irradiation therapy. Nor can the radiotherapeutic test—more prompt disappearance of the lesions in lymphosarcoma than in Hodgkin's disease under a similar dose of radium or roentgen-ray therapy—be always used as reliable guide in differential diagnosis. Highly cellular Hodgkin's disease in its early proliferative phase may be as sensitive or even more sensitive than late lymphosarcoma with secondary fibrotic changes.

Treatment of Lymphosarcoma and Hodgkin's Disease With very rare exceptions, chemotherapy, vaccine and toxin therapy have proved disappointing either as curative or palliative measures in either disease. Only in isolated lesions of the gastrointestinal tract has surgical treatment recorded some favorable results. As a whole, the most efficient local therapeutic agents are radium and the roentgen-rays. Although permanent cures have

* Gordon's biological differential diagnostic test requires further study and confirmation before it can be unequivocally accepted.

not been reported, moderate and, at times, marked palliation has been noted by numerous observers. Judged by final results, however, no sharp line of demarcation can be drawn between lymphosarcoma and Hodgkin's disease.

ILLUSTRATIVE CASE REPORTS

Case 1 Lymphosarcoma or Hodgkin's disease with primary symptoms of esophageal obstruction. C L, aged 53, had always enjoyed good health until the first week in October 1931, when he experienced difficulty in swallowing solid food. The difficulty became rapidly and progressively more marked. He vomited frequently and within the next six weeks lost 20 pounds in weight and considerably in strength. Medical examination including radiography and endoscopic examination of the esophagus resulted in a diagnosis of carcinoma of the esophagus. A biopsy taken from the constricted bulging area of the lower third of the esophagus was reported inflammatory tissue. However, so firmly impressed were the attending physicians with the primary cancerous nature of the esophageal lesion that another biopsy was done. This too failed to show any neoplastic growth.

On November 14, 1931, he was admitted to a large hospital in New York, with a diagnosis of carcinoma of the esophagus. He was emaciated and pale. The neck showed no enlarged lymph nodes, nor did any other regions of the body show any glandular enlargements. The chest and lungs were grossly negative. The heart was enlarged and a systolic murmur was heard at the apex. Abdominal examination was essentially negative. The liver and spleen were not enlarged. A blood count showed 4,980,000 red cells, 70 per cent hemoglobin, 10,000 white blood cells, 60 per cent polynuclears, 8 per cent band forms, 26 per cent lymphocytes, 6 per cent monocytes. Urinalysis was essentially negative. Radiographic examination of the chest showed "a dense homogeneous shadow extending out into the parenchyma from behind the left ventricle."

Diagnosis Lymphosarcoma of mediastinum with invasion of esophagus.

Course under roentgen-ray therapy and dilatation by bougies. Following dilatation of the esophagus by bougies and deep roentgen-ray therapy to the mediastinum very little relief of the obstructive symptoms was obtained. In the meanwhile the patient was rapidly developing symptoms of intracranial invasion evidenced by the appearance of headache, mental dullness, impaired vision, ocular palsies, nystagmus, papilledema, retinal hemorrhages and progressive narrowing of the visual fields. From the time of his admission to the hospital until the middle of December, a period of four weeks, he ran a fever reaching 101° F. Then a sharp rise occurred reaching 106° F. on December 20, 1931, the date of his death.

Antemortem Diagnosis Lymphosarcoma of mediastinum with invasion of esophagus and metastasis to the brain. (Figures 1 and 2)

Postmortem Diagnosis Lymphosarcoma of mediastinal lymph glands, both lungs, esophagus, stomach, peritoneum and brain.

Microscopic Examination Lymphosarcoma or Hodgkin's structure with lymphoblastic thrombi in vessels of tumor area in the lungs.

Comment The important clinical features deserving emphasis in this case are

1 The primary onset with symptoms of esophageal obstruction simulating primary cancer of the esophagus.

2 The absence of any peripheral lymph glandular enlargement during life and at necropsy.

*I am indebted to Dr. N. B. Selby, of New York, for the privilege of reporting this case.

FIG 2 (Case 1) Microphotograph of lymphosarcoma or Hodgkin's disease of the brain
(Courtesy of Dr C Davison)

3 The silent development of a mediastinal lymphosarcoma until compression of the esophagus first called attention to the lesion

4 The extremely rapid course after the appearance of first symptoms—the total clinical duration of the illness being only 10 weeks

5 The invasion of the vessels of the lungs, and hematogenous metastasis to the brain

6 The extensive invasion of non-glandular organs

7 The limitations of roentgen-ray therapy in such widely disseminated lymphosarcomatosis or Hodgkin's disease

8 The lack of sharply demarcated morphologic criteria in "atypical" lymphoblastoma to differentiate lymphosarcoma from Hodgkin's disease
The postmortem specimens were studied by experienced pathologists who were unable to decide whether the case belonged to the lymphosarcoma or the Hodgkin's group

9 The absence of any predisposing or exciting causes for the development of the disease

Case 2 Lymphosarcoma with primary symptoms of pulmonary disease D S, aged 42, was admitted to Montefiore Hospital, September 25, 1924

Chief Complaints Dry cough, shortness of breath, pain in the right chest, marked weakness, loss of appetite and weight, swollen glands Duration of symptoms 17 months

He had always enjoyed good health until March 1923, when he gradually developed a dry cough, shortness of breath, loss of appetite and strength Three months later he was admitted to a hospital in New York where a diagnosis of pleurisy with effusion was made This was apparently confirmed by aspiration of clear fluid from the left chest At the end of five weeks of hospitalization and medical treatment he had lost 16 pounds in weight, had become weaker and his respiratory complaints were unrelieved He left the institution of his own accord and on the advice of his family physician betook himself to the country for climatic treatment There, within a period of five weeks he gained 19 pounds in weight, but his respiratory distress was not relieved and became aggravated by the development of pain in the right chest Greatly discouraged he returned to the city and again consulted his family physician who found an increase in pleural effusion and advised immediate hospitalization

In December 1923, he was admitted to a prominent hospital in New York where, in addition to the pleural effusion, enlarged lymph glands were discovered in the neck and axilla A biopsy of one of the nodes was diagnosed as lymphosarcoma Only then, nearly 10 months after the first onset of his respiratory symptoms, was deep roentgen therapy first given to his chest and the affected glands Temporary improvement occurred followed by relapse In March 1924, he was referred to a special hospital for the treatment of neoplastic diseases Examination at this time showed, in addition to intrathoracic involvement, enlargement of all the superficial lymph glands and marked deterioration of his general condition Under further roentgen-ray therapy there was slight improvement followed by relapse

On admission to Montefiore Hospital, September 25, 1924, he presented an advanced case of lymphosarcoma with predominant respiratory symptoms In spite of his long illness he was well nourished The skin of the extremities showed numerous excoriations the result of pruritus All the superficial lymph glands showed discrete and conglomerate enlargements The teeth were carious The tonsils were greatly enlarged and congested The superficial veins of the anterior chest were dilated

There were signs of fluid in both pleural cavities. The heart showed moderate acceleration and a loud systolic murmur at the apex. The pulmonic second sound was accentuated. The abdomen was distended, tense, and showed the presence of a fluid wave. The intra-abdominal organs could not be palpated due to the tenseness of the abdominal muscles. Rectal examination showed a distinct irregular enlargement of the prostate gland, the left lobe being harder and larger than the right. The penis, scrotum and lower extremities were edematous.

The patient steadily grew worse and on October 3, 1924, expired in a condition of pulmonary edema.

Antemortem Diagnosis

- 1 Lymphosarcoma of superficial, mediastinal and retroperitoneal lymph glands
- 2 Lymphosarcoma of lung and pleura, possibly of tonsils and prostate

Postmortem Diagnosis

- 1 Lymphosarcoma of the parotid, submaxillary, cervical, mediastinal, abdominal, iliac and inguinal lymph glands
- 2 Extraglandular lymphosarcoma involving the appendix, appendices epiploicae, bronchi, cecum, dura, kidneys, liver, lungs, omentum, pituitary (figure 3), parotid, prostate (figure 4), seminal vesicles, spinal nerves, submaxillary salivary gland, spleen, thymus, tongue, tonsils, ureters
- 3 Compression of thoracic and abdominal aorta, vena cava and pelvic veins
- 4 Bilateral hydroureter and hydronephrosis
- 5 Localized pleural effusion (right)
- 6 Pulmonary congestion and edema
- 7 Ascites and edema of lower extremities
- 8 Herpes zoster (healing), fourth and fifth thoracic levels (left)

Gross Characteristics of the Tumor "The tumor wherever found consisted of an elastic, more or less firm, grayish white, moist, smooth, homogeneous tissue found in discrete and conglomerate nodules or continuous sheets. In places were small areas of yellowish and hemorrhagic necrosis. The tumor in the posterior cervical region was in the form of palpably discrete nodules, which on dissection were found united by thin tumor strands. The growth enveloped the salivary glands, replaced the tonsils and lingual nodes, from the supraclavicular nodes it grew down in wide chains into the upper thoracic regions (and on the right side formed a mass about 10 cm. in diameter at the medial angle of the apex of the lung), it formed a complete envelope about the right lung and on the left side invaded the posterior regions of the pleural coverings. At the bifurcation of the trachea the tumor tissue enveloped but did not replace the anthracotic root glands, and finally in a continuous sheet it grew on the anterior and lateral surfaces of the bodies of the vertebrae from the base of the skull down to the coccyx, filled the pelvis and covered its lateral walls, surrounding in its course the aorta, ureters, nerve fibers and pelvic vessels and organs. In addition, the tumor had infiltrated extensively the omentum, the appendices epiploicae, surrounded the appendix and cecum and right surface of the thoracic dura. The glands in the root of the mesentery, around the celiac axis, axillary and inguinal nodes were replaced by tumor."

Microscopically the structure was that of reticulum cell lymphosarcoma.

Comment The important points deserving emphasis in this case are

- 1 The absence of any predisposing or exciting causes for the development of the disease
- 2 The primary clinical onset with signs of pleurisy with effusion persisting for several months before discovery of enlargement of superficial lymph glands
- 3 The loss of 10 months before a positive diagnosis of lymphosarcoma was made from a biopsy of one of the superficial lymph nodes

FIG 3 (Case 2) Lymphosarcoma of pituitary gland

- 4 The frequent presence of hemorrhagic necrosis in the neoplastic lesions
- 5 The accompanying toxemia
- 6 The apparent local resistance of advanced lymphosarcoma to roentgen therapy even in the hands of expert radiotherapists
- 7 The comparatively short duration of the illness (17 months) in a man who previously enjoyed good health

8 The pulmonary mode of death

9 The clinical recognition of lymphosarcomatous invasion of the superficial, mediastinal and abdominal lymph glands, pleura and lungs and the failure to recognize the apparently silent and extensive invasion of the pituitary, tonsils, tongue, thymus, thoracic dura, spleen, liver, kidneys, appendix, cecum, omentum, prostate, seminal vesicles and ureter

10 The compression of blood vessels, nerves and hollow viscera

FIG 4 (Case 2) Lymphosarcoma of prostate

Case 3 *Hodgkin's disease with primary localization in cervical lymph glands and secondary invasion of the base of the brain with generalization of the disease* Isidor D, aged 42, first came under observation of the Radiotherapy Department of Montefiore Hospital on July 14, 1930. His chief complaints were Painful swelling in right neck, pain in the right side of the head, face and neck, attacks of dizziness and unconsciousness, hoarseness, shortness of breath, weakness, and loss of 20 pounds in weight.

Some five years ago, in the summer of 1925, he noticed enlargement of the right cervical glands not accompanied by any local or constitutional symptoms. He paid

no heed to this enlargement until several months later, when its progressive growth finally made him consult a physician. He was promptly referred to the Skin and Cancer Hospital, New York City, where a biopsy of one of the lymph nodes was reported typical Hodgkin's disease. During November and December 1925, he was given a series of roentgen-ray treatments to the neck with good result. The swelling completely disappeared and he felt entirely well. Bearing in mind, however, the treacherous and malignant character of Hodgkin's disease, the patient was advised to report every two or three months for follow-up examination. He followed the advice and for the next three and a half years felt entirely well and failed to show any evidence of local recurrence or any other manifestations of Hodgkin's disease.

In the summer of 1929, he began to have attacks of severe neuralgic pain in the right side of the head, face and neck, without any evidence of local swelling. These attacks kept growing in frequency and severity and a few months later were accompanied by vertigo and loss of consciousness. In the fall of the same year, during one of these attacks of unconsciousness he fell to the ground and suffered a lacerated wound of the scalp which required several sutures. Shortly thereafter he was referred by his local physician to one of the large hospitals in New York where he was demonstrated by a member of the teaching staff before a large body of postgraduate students as a severe case of hemicrania induced by dental caries and was strongly urged to have eight of the incriminating teeth removed. Anxious to get relief, he promptly followed the advice. Unfortunately, relief failed to follow. Instead of diminishing, the attacks became more frequent and severe and were followed by rapid deterioration of his general condition.

On February 6, 1930, he was admitted to another hospital in New York for a swelling in the right tonsillar region. A biopsy of the swelling failed to reveal any neoplastic growth. Without any further clinical study and investigation of the paramount problem which was distressing the patient, namely, the severe headache and the attacks of unconsciousness, he was discharged from the hospital, unimproved, on February 21, 1930.

On April 10, 1930, he was admitted to Mount Sinai Hospital, New York. By this time his general condition had become greatly deteriorated. He felt very weak, was emaciated and cachectic and complained of excruciating pain in the right occipital and parietal regions requiring large doses of sedatives for its relief. The right side of the face and neck was swollen. The posterior pharyngeal wall bulged on the right side while the uvula was shifted to the left. There were no other glandular swellings found on clinical examination. Laryngoscopic examination showed possible right recurrent nerve paralysis. A blood count showed red blood cells 4,920,000, polynuclears 70 per cent, lymphocytes 26 per cent, mononuclears 4 per cent, eosinophiles 0. He was given a series of radium and roentgen-ray treatments to the right side of the head and neck and was discharged from the hospital on May 13, 1930, only slightly relieved from the attacks of severe pain in the head and the attacks of unconsciousness.

When first seen at Montefiore Hospital on July 14, 1930, his chief complaints were (1) Recurring attacks of pain in the right side of the head, face and neck accompanied by vertigo and loss of consciousness—one year's duration. (2) Hoarseness—one year's duration. (3) Shortness of breath—one year's duration. (4) Partial deafness and discharging right ear—six months' duration. (5) Swelling of the right side of the face and neck. (6) Swollen glands in the left side of the neck—one month's duration. (7) Loss in weight from 130 pounds to 105 pounds. Examination revealed a pale, emaciated, middle-aged man with swollen right cheek. The right eye, pupil and right palpebral fissure were smaller than the left (Horner's syndrome). There was nystagmus of the right eye both in a vertical and horizontal direction. There was ptosis of the right upper lid and right facial paraly-

sis The tongue was deviated to the right. The right half of the tongue showed atrophy and fibrillary twitchings. There was partial deafness of the right ear. The gums were spongy. The uvula was deviated to the right. The pharynx failed to show any swelling. The eyes showed clear media and normal fundi.

Neck Several moderately enlarged discrete lymph nodes were present in the right and left cervical regions.

Shoulders The right shoulder was lower than the left and drooping. There was atrophy of the right shoulder girdle with some winging of the scapula.

Face The right side of the face was swollen, but no tumor masses could be detected in the right cheek or parotid gland.

Chest and Lungs Negative on physical examination. Radiographically, slight thickening of the right apical pleura was noted, otherwise the lungs and mediastinum were negative.

Heart Moderate tachycardia, otherwise negative. Roentgen examination shows normal contours of heart and aorta.

Abdomen Liver, spleen, kidneys, lymph nodes are not palpable. No distention or ascites.

The axillary, inguinal and femoral lymph glands are not enlarged.

Blood examination Red blood cells 4,900,000, hemoglobin 70 per cent, white blood cells 13,000, polynuclears 70 per cent, lymphocytes 26 per cent, eosinophiles 4 per cent.

Urinalysis is essentially negative.

Diagnosis Hodgkin's disease with intracranial invasion and infiltration into the posterior jugular fossa with involvement of the seventh, ninth, tenth, eleventh and twelfth cranial nerves after their emergence from the medulla, causing pressure against the cerebellum or restiform body. Of interest is the absence of any signs or symptoms of intracranial pressure with a lesion of the magnitude of this one and located in the posterior fossa.

Course under Roentgen Therapy Following a course of deep roentgen-ray therapy given to the skull and neck through multiple portals, the patient began to show satisfactory improvement. On September 9, 1930, hardly more than a month after deep roentgen therapy was started, his headaches were almost entirely relieved and the attacks of vertigo and unconsciousness were no longer present. The deafness of the right ear was diminishing. The right Horner's syndrome was still present and a slight right facial paralysis persisted. The deviation, atrophy and fibrillary twitching of the right half of the tongue remained unchanged. The uvula was still slightly deviated to the right. The cervical and axillary lymph glands were barely palpable. Parallel with the local improvement his general condition improved and within the next two months his weight rose from 99 pounds to 110 pounds.

In February 1931, he began to have pain in the left upper abdomen. Examination revealed, for the first time since the onset of his illness, enlargement of the spleen. Under irradiation the enlargement promptly disappeared. However, the protean and treacherous character of Hodgkin's disease was once again revealed by invasion of the superior mediastinum. Under further irradiation this new invasion was again controlled. In May symptoms of mediastinal and pulmonary invasion recurred and the liver became enlarged. In June definite radiographic evidence of infiltration of upper half of left lung was noted. Under further irradiation he improved but promptly relapsed. In August it was evident that the fatal issue was close at hand. He had signs of generalization of the disease with pulmonary and intra-abdominal invasion. He gradually lost ground and died on December 2, 1931, with symptoms of toxemia and respiratory embarrassment. Necropsy could not be obtained.

Comment Among the many interesting clinical features presented by this case, the following deserve special emphasis:

1 The primary and solitary clinical localization in the right cervical region for several months before a positive diagnosis of typical Hodgkin's disease was made by biopsy

2 The prompt response and complete disappearance of Hodgkin's lesions in the early proliferative cellular phase of the disease before the onset of necrosis and secondary fibrosis

3 The long remission or slow silent development of the disease without any demonstrable physical signs

4 The invasion of the base of the brain either by infiltrative invasion or lymphatic permeation from the involved glands in the right cervical region

5 The mistaken diagnosis of hemicrania of dental origin in the absence of any glandular swellings or any other active signs of Hodgkin's disease

6 The loss of nearly one year before a diagnosis of intracranial invasion of Hodgkin's disease was made, at which time destructive or degenerative changes had already taken place in several cranial nerves

7 The slight response to moderate irradiation and the greater response to more intensive irradiation

8 The imperfect results from irradiation therapy in the late stages of Hodgkin's disease in general and in the nervous system in particular, when advanced irremediable degenerative changes make recovery no longer possible

9 The subsidence of toxic symptoms and gain in weight under irradiation even in late Hodgkin's disease of five years' duration

10 The generalization of the disease while under careful medical observation and radiotherapeutic treatment

11 The inadequacy of our most powerful local physical agents—radium and roentgen therapy—to cope curatively with the disease when generalization has occurred even though the palliative results and prolongation of life obtained in this case cannot be gainsaid

Case 4 Lymphosarcoma with bone metastases and intracranial invasion F B, aged 37, was referred to the Radiotherapy Department of Montefiore Hospital, April 17, 1930

Chief Complaints Aching and throbbing pain in the left fronto-temporal and lower occipital regions aggravated by pressure and posture, shortness of breath on slight exertion, and epigastric pressure

In 1916, at the age of 23, he noticed a small, painless lump in the right inguinal region, which remained apparently stationary in size for the next 11 years. In 1927, some three years ago, the lump began to grow progressively larger, producing pain on walking. One year later, in June 1928, an exploratory laparotomy revealed a large deep-seated ilio-lumbar mass which on pathological examination was reported as lymphosarcoma. One month later he was referred for radiotherapy to Dr Maurice Lenz, of New York. At this time examination revealed no other sites of invasion with the possible exception of the cervical and axillary nodes which were slightly enlarged. Following a series of high voltage roentgen treatments to the right ilio-lumbar, inguinal and femoral regions the pain and swelling disappeared and the patient felt completely relieved.

On April 17, 1930, he first came under observation at Montefiore Hospital. His

chief complaints were (1) Aching pain in the left fronto-temporal region—eight months' duration (2) Occasional throbbing pain in the lower occipital region aggravated by pressure and posture—three months' duration (3) Shortness of breath on slight exertion (4) Epigastric pressure—a few months' duration

He was in good general condition, well nourished and only slightly pale. In the left fronto-parietal region there was a large, hard, tender, bony swelling, which on radiographic examination was found to be due to an extensive area of bone destruction involving the frontal and parietal bones (figure 5)

FIG 5 (*Case 4*) Lymphosarcoma of skull

The tongue, pharynx, tonsils, neck, mediastinum and lungs failed to show any neoplastic invasion on physical and radiographic examination. There were a few soft, slightly enlarged lymph nodes in the left axilla, which gave the impression of being non-neoplastic in nature. Careful abdominal palpation failed to reveal any enlargement of lymph nodes or spleen. The liver, however, was greatly enlarged, its upper border being at the fifth intercostal space, the lower border extending 12 cm below the costal margin. The surface was smooth, the edge sharp. Nodules and irregularities could not be detected. A blood count showed a slight secondary anemia. White blood cells 12,800, polynuclears 89 per cent, lymphocytes 7 per cent, mononuclears 2 per cent, eosinophiles 2 per cent. Urinalysis was essentially negative.

Neurological examination showed bilateral choked disk, left greater than right, with marked pigmentation and colloid degeneration which was more extensive on the right. The findings were interpreted as indicating metastatic invasion of the brain with increased intracranial pressure.

Course under Roentgen Therapy Following a series of roentgen-ray treatments to his skull and liver, he showed a rapid and satisfactory response. As early as July 1930, reexamination of the eyegrounds showed normal fundi. However, a few days later he began to have pain in the right shoulder. Radiographic examination revealed an area of bone destruction in the upper end of the shaft of the right humerus with periosteal thickening along the inner border of the shaft. This lesion also readily yielded to irradiation. Toward the end of the same year he felt well enough to resume his former occupation as counterman.

In the summer of 1931 he developed enlargement of the cervical, axillary, epitrochlear and inguinal lymph glands. The spleen was palpable 2 cm below the costal margin. On May 27, 1931, he complained of pain in the left inguinal region. The next day radiographic examination of the pelvis revealed areas of destruction in the right pubic bone and areas of sclerosis in the left pubic bone. In October the liver again became enlarged and was palpable 5 cm below the costal margin. Cautious irradiations controlled the above lesions. In February 1932, he complained of pain in the left chest. Radiographic examination revealed partial consolidation of the left lower lobe with a small pleural effusion. Under irradiation the pulmonary lesion cleared up entirely within a few months. In January 1933, he developed a tender mass over the sternum. This likewise promptly disappeared under irradiation. Toward the end of April he had a recurrence of the left sided pulmonary invasion with pleural effusion, which again yielded to roentgen-ray treatment. Examination in July still found him in good general condition. In spite of extensive high voltage roentgen-ray therapy given over a period of three years, a complete blood count done on July 5, 1933 showed no change from the one on the date of admission in April 1930. The red blood cells were 3,870,000, the hemoglobin 75 per cent, the white blood cells 5,200, the polynuclears 69 per cent, the lymphocytes 25 per cent, mononuclears 5 per cent, eosinophiles 1 per cent.

In August 1933, he began to lose ground rapidly. The liver enlarged to about 10 cm below the costal margin. The invasion of the lung and pleura recurred in aggravated form. There were multiple areas of bone invasion. He grew pale and weak. His cardiac and respiratory embarrassment progressively increased and finally, toward December 1933, he passed into a condition of coma and died. A necropsy could not be obtained.

Comment The outstanding clinical characteristics of this case are

- 1 The presence of an apparently stationary enlargement of the right inguinal lymph glands for 11 years before they assumed a rapid and progressive growth and intra-abdominal invasion and extension.

- 2 The lapse of one year (or should we assume 12 years?) before laparotomy revealed an extensive intra-abdominal lymphosarcomatosis continuous with the inguinal invasion.

- 3 The rapid response of long-standing extensive intra-abdominal lymphosarcomatosis to high-voltage roentgen-ray therapy.

- 4 The apparently hematogenous route of metastases as evidenced by the invasion of the skull—and later other bones—without any demonstrable glandular or other soft tissue lesions in the vicinity.

- 5 The generalized yet discrete invasion of organs and tissues.

6 The order of clinical progression (a) inguinal nodes, (b) lumbar nodes, (c) skull, (d) cranial cavity, (e) brain, (f) liver, (g) right humerus, (h) left humerus, (i) axillary lymph nodes, (j) pubic bones, (k) spleen, (l) epitrochlear lymph nodes, (m) lung and pleura, (n) sternum and ribs

7 The comparatively slight toxic or constitutional symptoms until a few months before the end in spite of many years of widespread lymphosarcomatous lesions which were actively treated by roentgen-rays. The blood examination in July 1933, showing apparently no changes within a period of three years of repeated roentgen-ray therapy over bones, liver, lungs and lymph nodes, is one of the most instructive in clinical medicine. It shows that irradiation carefully controlled by clinical and blood studies may be administered for years without any demonstrable injury to the hemopoietic organs in a disease in which they are greatly exposed to injury.

8 The long duration—six to 17 years—of generalized lymphosarcomatosis in rare cases.

9 The continued spread and generalization of the disease under very careful clinical observation and treatment with roentgen-rays stresses the important fact that no local mode of treatment in lymphosarcoma can be permanently curative when the disease becomes generalized, although even then prolongation of life in comfort for several years may be achieved by judicious and efficient radiotherapy.

Case 5 Hodgkin's disease with skeletal invasion and pathologic fracture of the spine. M. G., aged 32, was admitted to Montefiore Hospital, July 8, 1927, with a diagnosis of Hodgkin's disease with pathologic fracture of the third lumbar vertebra.

In February 1924, without any apparent predisposing or exciting causes, he developed painless swellings in the neck which gave rise to no local or constitutional disturbance. Six months later he began to have substernal pain, cough and blood-streaked sputum. He made the round of several clinics and hospitals where he was treated medically with indifferent results. In the summer of 1926 his symptoms became more marked and, in addition, he suffered pain in the abdomen and across the lumbar spine. Frequently he felt nauseated and vomited. His appetite was gone and he lost weight progressively. In April 1927, he was admitted to a large hospital in New York where a diagnosis of Hodgkin's disease with pathologic fracture of the third lumbar vertebra was made. Examination of the blood at this time showed 2,000,000 red cells, 36 per cent hemoglobin, 5,600 white blood cells, 59 per cent polynuclears, 38 per cent lymphocytes, 3 per cent mononuclears. Following roentgen-ray therapy to his chest and spine there was very little improvement in symptoms and on July 8, 1927, he was transferred to Montefiore Hospital.

Examination revealed a very anemic, dyspneic, asthenic, jaundiced and cachectic individual. The cervical, axillary and inguinal lymph glands showed discrete and conglomerate enlargements. Dullness and crackling râles were present over the base of the right lung. There was a systolic murmur at the apex and a diastolic murmur at the base of the heart. The heart rate was moderately accelerated. The blood pressure was 90 systolic and 28 diastolic. The abdomen was distended and showed a fluid wave. The liver and spleen were moderately enlarged. The spine was tender from the second lumbar vertebra down to the coccyx. Over the fourth lumbar vertebra there was a tender bony swelling. The legs were edematous. A blood count on July 8, 1927 showed 1,900,000 red blood cells, 26 per cent hemoglobin, 3,800 white blood

FIG 6 (Case 5) Invasion of adrenal, periadrenal tissues and blood vessels in Hodgkin's disease

FIG 7 (Case 5) Higher magnification showing invasion of blood vessel in periadrenal tissues

cells, 68 per cent polynuclears, 29 per cent lymphocytes and no abnormal cells. Urinalysis gave a heavy trace of albumin and no other abnormal findings.

The patient steadily went down hill with symptoms of cardiac and respiratory embarrassment and died on August 19, 1927.

The antemortem clinical diagnosis was (1) Hodgkin's disease involving all the lymph glands of the body, (2) Hodgkin's disease of spleen, liver and spine.

Necropsy revealed (1) Hodgkin's disease of the superficial lymph glands and of bronchial and retroperitoneal nodes (2) Hodgkin's invasion of the spleen, head of the pancreas and left suprarenal gland (figures 6 and 7) and third lumbar vertebra (3) Aorta, vena cava and iliac vessels embedded in nodular masses (4) Infarction of spleen with moderate amyloid infiltration in places (5) Bronchopneumonia (6) Serofibrinous pleuritis, pericarditis and peritonitis (?) with effusion.

Microscopic examination Hodgkin's disease with few eosinophiles.

Comment The salient clinical features deserving emphasis are

- 1 The absence of any predisposing or exciting causes
- 2 The presence of painless and symptomless swellings in the neck for six months before the development of any evidence of intrathoracic invasion
- 3 The marked secondary anemia, the absence of eosinophiles and monocytes in the last blood examination
- 4 The presence of pain in the lumbar spine for many months before the discovery of the pathologic fracture of the third lumbar vertebra
- 5 The absence of any febrile stage during the patient's six weeks' stay at Montefiore Hospital
- 6 The poor response to radiation therapy of advanced Hodgkin's disease

Case 6 Primary lymphosarcoma of spleen with secondary paraplegia S I, aged 43, was admitted to Montefiore Hospital, December, 27, 1929, with paraplegia as the chief complaint.

In February 1928, he developed progressive weakness, occasional abdominal pain, anorexia, belching and loss in weight. Toward the end of 1928 epigastric pain after meals became so marked that he voluntarily began to restrict the intake of food. However, not until the summer of 1929 did he seek any medical aid. Finally on July 18, 1929, he was admitted to Bellevue Hospital where a large splenic tumor was removed. The pathological diagnosis was lymphosarcoma of spleen. The patient made a good post-operative recovery and was discharged from the hospital on August 18, 1929. A few days later he developed pain in the small of the back radiating down both lower extremities, and difficulty in walking. On September 19 he was readmitted to Bellevue Hospital in a very poor general condition. He was slightly jaundiced and appeared cachectic. Radiographic examinations failed to reveal any metastatic foci in the lungs or spine. A blood count done on September 16 showed 4,000,000 red blood cells, 75 per cent hemoglobin, 8,000 white blood cells, 60 per cent polynuclears, 22 per cent lymphocytes, 14 per cent transitionals, 2 per cent eosinophiles and 2 per cent basophiles. The blood Wassermann test was negative. Urinalysis was essentially negative.

His condition rapidly grew worse. He suffered continuously from pains in his back and legs and gradually grew weaker. In November definite paraplegia was noted. He was then transferred from Bellevue Hospital to Montefiore Hospital, where he was admitted on December 27, 1929, in a pitiable and helpless condition with paraplegia and decubitus ulcers. He was emaciated and jaundiced. The peripheral lymph glands were not enlarged. The chest and lungs were negative on physical and

radiographic examination The heart was not enlarged, the rate regular, 72 per minute. The liver was palpable 1 cm below the costal margin. There were no intra-abdominal masses and ascites was not present. Both lower extremities were completely paralyzed. Neurological consultation elicited a diagnosis of lymphosarcomatous metastatic invasion of the cauda equina possibly by extension from the spine, and deep roentgen-ray therapy was suggested. On January 6, 1930, radiographic examination of the skeleton failed to show any vertebral involvement. There was evidence of an old fracture of the ninth and tenth left ribs. There was an area of bone destruction in the lower end of the right ilium. There was a fracture through the upper end of the shaft and lesser trochanter of the left femur.

Course under Roentgen Therapy Following two erythema doses of deep roentgen therapy over the lumbo-sacral spine there was some diminution of the pain in the back and some improvement in the paralysis of the lower extremities. However, the patient gradually went down hill with symptoms of progressive asthenia and wasting and expired on May 29, 1930.

Necropsy revealed lymphosarcoma of retroperitoneal lymph glands and liver and active tuberculous lesions in the upper lobes of both lungs in which lymphosarcomatous lesions were absent. It is to be regretted that the brain and cord were not removed and sections of bone were not secured for pathologic examination.

Comment The salient clinical features of this case are

- 1 The primary clinical localization of lymphosarcoma in the spleen with secondary invasion of the retroperitoneal lymph nodes, cauda equina and liver

- 2 The failure of splenectomy 18 months after the onset of first clinical symptoms to affect the further course of the disease which was chiefly dominated by the invasion of the liver and cauda equina, with production of paraplegia, decubitus ulcers and toxemia

- 3 The marked wasting and cachexia of toxic origin

- 4 The associated tuberculosis of the lungs with no demonstrable foci of lymphosarcoma in the affected lungs and no tuberculosis in the lymphosarcomatous organs and structures

- 5 The failure of roentgen therapy to affect the late compressive phenomena of lymphosarcoma in nervous structures when irreparable degenerative changes have taken place

Case 7 Hodgkin's disease with primary and predominant broncho-pulmonary symptoms A H., aged 32, was admitted to Montefiore Hospital, June 28, 1928, with the following chief complaints: Cough and expectoration, shortness of breath, night sweats, poor appetite, loss of weight and strength, pain in the upper abdomen and across the small of the back, swollen glands in the cervical, axillary and inguinal regions. Duration of symptoms one year.

Family History Negative

Previous History In 1917, ten years before the onset of his present illness, he developed an acute respiratory infection which was suspected to be tuberculous in origin. At the end of three months he made a good recovery and, with the exception of frequent head colds, had enjoyed good health until the onset of the present illness.

Present Illness In June 1927, he gradually developed cough, expectoration, shortness of breath, night sweats, loss of appetite and pain in the upper abdomen and across the small of the back. He lost weight rapidly and grew progressively

weaker One month later his family physician made a diagnosis of bronchitis and advised a stay in the country for a few weeks A few days after the medical consultation he noticed for the first time painless enlargement of the glands in the left side of the neck He left for the mountains and within a few weeks felt greatly relieved from his respiratory complaints and gained some weight and strength, but the swelling of the glands in the left side of the neck did not recede and the glands in the right side of the neck became enlarged However, the glandular enlargements gave rise to no local discomfort, and on return to the city in August 1927, he felt sufficiently improved to resume his occupation as garment worker Gradually his respiratory symptoms recurred in an aggravated form, and toward the end of December 1927 he was forced to discontinue his work

On January 28, 1928, he was admitted to a large hospital in New York where a radiographic study revealed a mass at the root of the right lung The cervical, axillary and inguinal glands and the spleen were moderately enlarged Several blood counts showed a slight secondary anemia The white blood cells varied from 6,400 to 3,700 per cu mm, polynuclears 75 to 90 per cent, eosinophiles 2 to 3 per cent, mononuclears 2 to 7 per cent, small lymphocytes 8 to 27 per cent

A biopsy of one of the cervical lymph nodes was diagnosed as atypical Hodgkin's disease

Following a series of roentgen-ray treatments to the left cervical, anterior mediastinal and left inguinal regions there occurred a diminution in size of the irradiated glands followed by an increase of weakness and abdominal and lumbar pain Slowly and progressively he lost ground His cough, expectoration and dyspnea increased His abdomen became more painful His ankles swelled and he became entirely bedridden

On admission to Montefiore Hospital on June 28, 1928, he was emaciated and cachectic The skin was darkly pigmented The parotid, cervical, axillary and inguinal lymph glands were moderately enlarged and matted together There were signs of a moderate pleural effusion on physical and radiographic examination The heart was not enlarged The rate was 135 per minute The blood pressure was 90 systolic and 60 diastolic The abdomen was tense and distended The liver and spleen were palpable 4 cm below the costal margin Both ankles were edematous

For the next four weeks he ran an irregular fever ranging between 98 and 104 His respiratory embarrassment increased Fluid developed in both pleural cavities His blood pressure sank to the low level of 66 systolic and 38 diastolic and on July 28, 1928, he died with symptoms of congestive heart failure

Necropsy revealed (1) Hodgkin's disease of the cervical, axillary, mediastinal, mesenteric and retroperitoneal glands (2) Hodgkin's invasion of spleen and lung (3) Compression of the thoracic duct with chylous ascites (4) Compression and obliteration of the cystic duct (5) Compression of the common duct (6) Compression of the left renal vessels with secondary atrophy of left kidney (figure 8)

Microscopically the lesions were typical of advanced Hodgkin's disease The lymph glands presented massive necrosis with complete replacement by fibrous tissue There were many endothelioid cells and a few Dorothy Reed giant cells but no eosinophiles

The spleen presented a necrotic mass in a fibrinous network at the periphery of which there were areas of hemorrhage and others of round cell fibroblastic infiltration with a few polynuclears and occasional endothelioid and erythrophage cells but no eosinophiles In one area the Hodgkin's cells infiltrated and partly formed the lining of a blood sinus

The left lung, in addition to a lesion of Hodgkin's disease, presented a large sharply demarcated infarct with areas of parenchymatous atrophy and replacement by loose fibrous tissue and necrosis and hemorrhage in the center

Comment The salient clinical features of this case are

- 1 The primary clinical onset with broncho-pulmonary symptoms persisting for several weeks before enlargement of glands in the neck
- 2 The delay of eight months before a diagnosis was made in a patient who was rapidly developing toxic and compressive Hodgkin's disease

FIG 8 (Case 7) Atrophy of left kidney due to compression of renal vessels by enlarged nodes of Hodgkin's disease

- 3 The poor response to roentgen therapy in late and severely toxic and necrotic Hodgkin's disease

4 The marked necrosis of spleen and lymph nodes, the severe toxemia, the irregular remittent fever and the marked hypotension without any evidence of Addison's disease

- 5 The compression of the thoracic duct with the production of chylous ascites

6 The compression of the cystic and common bile ducts with the production of hydrops of the gall-bladder and fatty degeneration of the liver

7 The compression of the left renal vessels with secondary atrophy of the kidney

8 The brief duration of the illness which was shorter by four months than in the preceding case of lymphosarcoma

9 The absence of tuberculosis or any other etiologic factor to account for the development of the disease and its rapid dissemination and short duration

Case 8 Primary lymphosarcoma of stomach A B, aged 55, was admitted to the hospital August 24, 1930, complaining of marked weakness, loss of weight, nausea, vomiting and a painful mass in the upper abdomen

In August 1928, without any apparent cause, he began to lose weight and strength. A few months later anorexia, nausea and occasionally vomiting made him consult a local physician. The diagnosis was doubtful and the remedies were ineffectual. In May 1929, he applied to a large hospital in New York, where his marked weakness and low blood pressure led to a diagnosis of Addison's disease and for a period of three months he was given adrenalin injections and other forms of medical treatment. He failed to improve and noticed in addition the gradual development of a painful mass in the upper abdomen.

In February 1930, he was admitted to another large hospital in New York in a markedly emaciated and cachectic condition. His skin was bronzed. There was a swelling in the nasopharynx and numerous small, hard nodes in the right supra-clavicular region. In the left upper quadrant of the abdomen and epigastrium was found a movable, firm, smooth, rounded mass which was non-tender and was thought to be either intragastric or intracolonic. A blood count showed a secondary anemia. The blood pressure was 80 systolic and 60 diastolic.

Roentgen studies of the gastrointestinal tract revealed evidence of either an intragastric or extragastric lesion. Gastrophotography suggested an intragastric lesion. No free hydrochloric acid was present in the stomach even after histamine. A diagnosis of gastric neoplasm, probably on the posterior wall, was then made.

A biopsy from a soft, white, large, glistening swelling involving the posterior pillars of the fauces was reported as showing a tumor of the Schminke type. In order to determine the local involvement of the naso-pharyngeal tumor, a roentgen-ray examination of the skull was made and was reported as showing findings in the sella turcica suggesting pituitary neoplasm. There were no neurological findings suggestive of this. The visual fields were normal.

Radiotherapy of the nasopharyngeal tumor caused a marked shrinkage and almost entire disappearance. Similar results were obtained with the abdominal tumor which shrank to one-fourth its former size. An operation upon the abdominal mass had been suggested both for diagnosis and treatment but the surgeons considered the patient a bad risk and so the radiotherapy was carried out.

The patient improved remarkably in strength and general well-being, and was discharged from the hospital. The final diagnosis was (1) Schminke tumor of nasopharynx (2) Pituitary neoplasm (3) Gastric neoplasm. Interrelationship of the three was not established.

He remained under observation and treatment at the radiotherapy department of the hospital until the summer of 1930, when he noticed two painless masses developing over the anterior chest. From this date his health began rapidly to decline and his symptoms recurred in aggravated form. On admission to Montefiore Hospital on August 24, 1930, he complained of weakness, loss of weight, nausea and vomiting,

pain and swelling in the upper abdomen and lumps in the chest. He was emaciated and cachectic. The skin showed a brownish pigmentation. He was toothless. The pharynx was congested but no masses were present. There were no enlarged glands in the neck. Over the second and third costo-chondral articulations were several small, hard, immovable masses apparently springing from the periosteum. In both axillae a few small, hard glands were present. The apices of both lungs gave a dull percussion note. The heart was rapid but otherwise negative on examination. In the upper abdomen an indefinite mass was felt. The liver and spleen were not palpable. Rectal examination revealed a hard, tender mass in the region of the prostate. A blood count showed red blood cells 4,150,000, hemoglobin 65 per cent, white blood cells 11,510, polynuclears 65 per cent, lymphocytes 32 per cent, undifferentiated cells 3 per cent. Urinalysis was essentially negative.

Radiographic studies. Chest. Apical thickening due to old tuberculosis and infiltrative mass in the region of the right upper lobe, extending out from the mediastinum a distance of about 1.5 inches. There is an extension from the hilum into the left upper lobe. A small pleural effusion is present at the left base.

Gastrointestinal Tract. Irregularity of the cardiac end of the stomach suggestive of malignant neoplasm. Barium enema of colon negative.

Skull. Sella turcica three times normal size. Thinning of floor and of posterior clinoid processes. Appearance is strongly suggestive of pituitary neoplasm.

Urinary Tract. Uroselectan test showed dilatation of pelvis and calices of right kidney. **Diagnosis.** Right hydronephrosis.

Analysis of the clinical and laboratory findings led to the following tentative diagnoses by different members of the attending and house staff: (1) Hodgkin's disease, (2) Hypernephroma with metastases, (3) Cancer of the bowel with metastases, (4) Cancer of the prostate with metastases.

On September 11, 1930, a biopsy of one of the nodes in the left axilla elicited the report: "All normal lymphatic structure is gone. The entire lymph node is replaced by closely packed round cells which infiltrate the capsule of the surrounding fat tissue. These cellular elements are uniformly small, the nuclei are fairly deeply staining. There is very little variation in the size of the cells. The nuclear elements are rich in chromatin. A vein outside of the lymph node is filled with a large number of lymphocytes. This is extremely suspicious of lymphatic leukemia" (Figure 9). However, a restudy of the blood showed 11,660 white blood cells, 74 per cent polynuclears, 20 per cent lymphocytes and 6 per cent undifferentiated cells.

The third week in September his respiratory symptoms became more marked and on the twenty-fifth of the month he died with symptoms of a terminal bronchopneumonia.

Necropsy revealed: (1) Lymphosarcoma of stomach with metastases to regional, retroperitoneal, periaortic, posterior and anterior mediastinal lymph glands, (2) Diffuse lymphosarcomatous invasion of entire peritoneum with hemorrhagic ascites, (3) Invasion of left spermatic cord, (4) Right hydronephrosis, (5) Invasion of thymic fat tissue, parietal pericardium, right lung and pleura, (6) Bronchopneumonia right lung, (7) Bilateral otitis media and mastoiditis, (8) Basophilic adenoma of pituitary.

Comment. Among the many interesting features presented by this case, the following deserve special emphasis:

1 The onset with gastrointestinal symptoms, marked asthenia and low blood pressure, which led to a mistaken diagnosis of Addison's disease.

2 The presence of a lymphosarcomatous tumor in the nasopharynx which morphologically presented the cellular structure of a Schminke tumor or lymphoepithelioma.

FIG 9 (Case 8) Invasion of capsule and blood vessel in lymphosarcoma of lymph node

3 The failure to recognize the lymphosarcomatous origin of, at least, some Schminke tumors led to failure to recognize the nature of the underlying abdominal tumor

4 The improvement that followed roentgen-ray therapy of the pharyngeal and abdominal tumors in a late case of generalized lymphosarcomatosis

5 The pleomorphism of lymphosarcoma in some cases The biopsy specimen from the nasopharynx was reported as lymphoepithelioma, while the one from the left axilla bore the characteristics of lymphatic leukemia Other areas from the intestines and the stomach gave the typical structure of reticulum cell lymphosarcoma and Hodgkin's disease

6 The extensive invasion of extra-glandular organs and tissues which dominated the clinical course of the disease

7 The toxic and pulmonary mode of death

Case 9 Lymphosarcoma of the transverse colon well four years after resection
B W, aged 57, was admitted to Montefiore Hospital, May 23, 1931, complaining of cramps in the abdomen, constipation and loss of 20 pounds of weight

He was in good health until October 1930, when he began to suffer from constipation, belching of gas, rumblings in the abdomen, loss of appetite and weight He consulted a local physician who diagnosed constipation and prescribed laxatives He failed to improve and in March 1931, applied to a large hospital in New York, where after two months of observation and treatment a diagnosis of a malignant neoplasm was made

On admission to Montefiore Hospital on May 23, 1931, he was well nourished There was no superficial lymph node enlargement The heart and lungs presented no abnormality on physical and radiographic examination The blood pressure was 144 systolic and 82 diastolic The abdomen was distended and tense In the region of the splenic flexure an oval movable mass was felt On radiographic examination obstruction at the splenic flexure was present with dilatation of the transverse colon A blood count showed 3,200,000 red blood cells, 55 per cent hemoglobin, 8,000 white blood cells A diagnosis of carcinoma of the splenic flexure was made and on June 22 1931, a resection of an ulcerated obstructive distal transverse colon was done The mesenteric glands were not enlarged and the liver was free from any invasion The pathologic examination of the removed tumor led to a diagnosis of lymphosarcoma The patient made a good recovery and has remained well until the present date Repeated clinical and roentgen examinations during the past four years have failed to show any evidence of lymphosarcomatous recurrence or invasion of any other organs and structures

Case 10 Lymphosarcoma of mediastinum well three years after irradiation
F R, aged 53, first came under observation at the Radiotherapy Department of Montefiore Hospital on May 23, 1931

The first week in April 1931, she first noticed enlargement of the left cervical lymph glands She would not have paid any attention to it, but she had headaches and spells of dizziness due to long-standing hypertension and therefore consulted her family physician He noticed the enlarged glands and had her chest roentgen-rayed Examination revealed enlarged bronchial glands A biopsy of one of the cervical glands was diagnosed as probable lymphosarcoma

When first examined at the Radiotherapy Department of Montefiore Hospital on May 23, 1932, she was well nourished and did not appear ill The teeth, tongue and throat were negative In the left supraclavicular region there was a tender mass measuring 6 by 6 cm, with a recent scar in the center It was firm in consistency and fixed to the underlying structures In the left axilla there was one enlarged lymph

node 3 by 3 cm in size and rubbery in consistency. There was upper mediastinal dullness. The lungs failed to show any gross abnormality. The heart was enlarged. The aortic second sound was accentuated. Blood pressure 165 systolic and 120 diastolic. There were no murmurs or acceleration. The abdomen was not distended. The spleen was not enlarged. The liver was palpable 3 cm below the costal margin. Vaginal examination revealed a fibroid uterus corresponding in size to a two months' pregnancy. Rectal examination was negative.

Laboratory Data Radiographic examination of the chest revealed a distinct enlargement of the superior mediastinum on both the right and left sides and the nodes at the right hilum showed marked enlargement. The appearance was most suggestive of Hodgkin's disease. A blood count on May 24, 1932 showed 4,750,000 red blood cells, 80 per cent hemoglobin, 9,500 white blood cells, 65 per cent polymorphonuclears, 29 per cent lymphocytes, 3 per cent each of eosinophiles and monocytes. Urinalysis was essentially negative.

Course under Radiation Therapy Following a series of high voltage roentgen-ray treatments to the mediastinum and cervical region the enlarged glands completely disappeared and have as yet shown no recurrence.

Comment The favorable results obtained in the last two cases of lymphosarcoma—in one by operation and in the other by roentgen-ray therapy—stress the fact that lymphosarcoma is not always from the outset a widely disseminated disease. It may for a time remain localized in one or a few organs or tissues. In such cases operation or irradiation may completely remove the local disease. A freedom from recurrence for three or four years must not lull us into an undue feeling of security as to permanent cure. Recurrence may take place. Hence we shall periodically carefully reexamine these patients and at the first signs of recurrence institute appropriate therapy. Until such time, however, we must be grateful for the excellent results now lasting three and four years respectively in definitely proved cases of lymphosarcoma, not differing clinically from many other similar cases which rapidly succumbed to the disease.

SUMMARY AND CONCLUSION

1 Lymphosarcoma and Hodgkin's disease most frequently manifest themselves clinically by invasion of lymph nodes and spleen. However, their malignant invasion is not confined to lymphoid organs and structures only. They are protean diseases and invade every organ and tissue of the human body.

2 Extra-glandular involvement by lymphosarcoma and Hodgkin's disease is not always an extension or a metastasis from primary invasion of lymph glands or spleen. Primary and predominant extra-glandular lymphosarcoma and Hodgkin's disease have been reported by numerous careful observers.

3 There are no pathognomonic clinical signs of lymphosarcoma and Hodgkin's disease. Hence, extra-glandular involvement of either disease has frequently been overlooked and mistaken for non-neoplastic conditions.

4 Both diseases are characterized not only by marked invasion, proliferation, replacement and compression of organs and tissues but also by necrotization, ulceration, toxemia, cachexia and febrile reaction.

5 A febrile reaction, especially of the relapsing type, has been more frequently observed in Hodgkin's disease but is by no means rare in lymphosarcoma

6 Both diseases may spontaneously run an acute, a subacute or a chronic course

7 There are no pathognomonic clinical signs by means of which Hodgkin's disease can be differentiated from lymphosarcoma. The only method of differentiation is on the basis of morphologic microscopic criteria, which are not always conclusive

8 Gordon's biological differential diagnostic test to differentiate Hodgkin's disease from lymphosarcoma necessitates the use of a biopsy and requires further study and confirmation before it can be unequivocally accepted

9 The etiology of lymphosarcoma and Hodgkin's disease still remains obscure. Gordon's claim for a filtrable virus as the cause of Hodgkin's disease still needs confirmation

10 There is no specific method of treatment for either disease. Chemotherapy, vaccine and toxin treatment, surgery and irradiation are purely palliative methods which, in selected cases, have produced favorable results with freedom from clinical evidence of disease for many months and years

11 Efficient and judicious radium and roentgen-ray therapy, always combined with skillful medical management, are the most important physical agents at our command today to cope with these two highly malignant diseases

12 To obtain favorable results in either disease by the methods available today, early diagnosis must be made before irremediable destruction or compression of organs occurs or before widespread metastases overwhelm the patient. Both lymphosarcoma and Hodgkin's disease invade, infiltrate and destroy organs and tissues not only by direct extension but also by lymphogenous and hematogenous metastases as in epithelial cancer. Hence, early recognition is absolutely essential for successful irradiation therapy or any other form of local treatment. Any delay of days or weeks, not to say months, is very hazardous

13 In doubtful cases where a biopsy is unobtainable, the radiotherapeutic test may be greatly helpful not only in arriving at a diagnosis but also in relieving the patient

14 The clinical course, the mode of death, the results of chemotherapy, vaccines, toxins, radium, roentgen-ray therapy and surgery as observed in lymphosarcoma and in Hodgkin's disease run very closely parallel. The prognosis in both diseases is similar

15 Hodgkin's disease varies in no fundamental clinical characteristics from lymphosarcoma. Whatever clinical variations it may present at times are merely variations that one may encounter in any disease affecting different individuals under different constitutional and environmental conditions

THE PROPHYLACTIC AND THERAPEUTIC VALUE OF CONVALESCENT SERUMS IN SOME OF THE ACUTE INFECTIOUS DISEASES ~

By WILLIAM THALHIMER, M D , F A C P , *New York, N Y*

TODAY there is a steadily increasing interest in both the prophylactic and the therapeutic value of various convalescent serums. It is, however, extremely difficult to secure accurate information of the value of any agent in preventing acute infectious diseases. This is because of the many variables, having to do with the intimacy, degree and time of contact with an infectious individual, the degree and stage of infectivity of the patient, the relative resistance of the exposed individual, etc. Therefore, although the number of reports of well controlled prophylactic studies is increasing, the profession still views these efforts at prevention with some natural skepticism.

In the therapeutic use of convalescent serums in the acute exanthemata an analysis of the results can be more rigorous, but even here skepticism of physicians prevails. The reason for this attitude is probably not far to seek. The supply of convalescent serums has been meagre, except in a few places, and only a few large series of cases including the requisite controls have been published. Furthermore, in the usual infections of childhood, with which every doctor has had all too ample experience, each physician prefers to evaluate each prophylactic and therapeutic agent himself. Since convalescent serum has not been generally available, the profession has not been able to gain personal experience with its use. Even those who accepted the favorable conclusions of others, could not obtain convalescent serums in sufficient amounts for use in hospitals and private practice. In the regions where convalescent serums have been available, general practitioners and pediatricians are using these serums more and more, indicating in this way that they find them valuable.

It has been demonstrated at several convalescent serum centers that sufficient scarlet fever and measles serums can be obtained for widespread use in each center provided with a center. Each state could also supply its own needs by a comparatively simple expansion and by placing the centers in strategically situated cities.

The local departments of health have given their very necessary cooperation in Chicago, Milwaukee, Philadelphia, Providence, and recently in New York. The Detroit Department of Health deserves the credit of having established its own Convalescent Serum Center, this being the oldest large center in the United States. A number of European cities also have had similar organizations for years.

The relatively small fund needed for equipping and initiating each center is easily secured, even today. The donors furnishing serum receive com-

* Read at the Detroit meeting of the American College of Physicians, March 3, 1936

pensation Only Wassermann and Kahn negative serums are used and the pooled serum is always passed through a Berkefeld filter before bottling The rigid technic and sterility tests of the U S Public Health Service are followed The serums retain their potency for at least 6 to 12 months, when kept at 4° Centigrade

Each center can become self-supporting by making a moderate charge for serum furnished for private patients, and at the same time provide municipal infectious disease hospitals with needed serum without cost These centers, with the cooperation of health departments, physicians and hospitals, can also investigate the possible value of convalescent serums for other infectious diseases, a field demanding immediate and intensive study

MEASLES CONVALESCENT SERUM

Although Cenci apparently was the first, in 1901 and 1906, to use convalescent serum for passive immunization, and reported favorable results in the few instances where it was used, it was not until 1918 that Nicolle and Conseil published their marked success in larger series of cases It is important to realize that Park and Zingher in this country, independently used the same method in the same year, although they did not publish their results until 1924 Many publications have followed, too many to quote here, especially as a number of excellent reviews are available* All have shown the definite value of passive immunization with convalescent serum and some of its limitations

In order to secure complete protection, the serum should be given intramuscularly within five days of exposure, and in a sufficient amount, that is one cubic centimeter for every year of age From 70 to 90 per cent complete protection is then secured The reason for this percentage difference undoubtedly lies in the variables already mentioned, as well as in the size and timing of dose Protection not infrequently occurs when serum is administered up to the eighth or ninth day after exposure, and though such effects cannot be relied on such a late attempt to obtain protection is advisable with debilitated or very young children With injections of serum between the fifth and eighth days, the result usually is attenuation to a mild or even insignificant attack, sometimes difficult to recognize, which apparently produces as lasting an immunity as the full blown disease Modified measles is rarely accompanied or followed by complications This limitation of the infection by delayed passive immunization may be the method of choice with exposed healthy children over five years of age However, everyone agrees that all debilitated children regardless of their age, and all children under five years, should be completely protected, if possible It is in these individuals that measles causes a high mortality because of complicating conditions, such as pneumonia, mastoiditis, etc Because of the benign nature of attenuated measles in an otherwise healthy child and because of the advantage of the

* For complete review of the literature through 1930, see Vol VII, of the Annals of the Pickett-Thomson Research Laboratory

permanent immunity conferred, an English observer has made a humorous suggestion with serious intent. He proposes giving "Measles teas," that is, inviting healthy children to have "tea" with a child during the infectious stage and later giving attenuating doses of convalescent serum between the fifth and eighth days or, better still, one-half the standard dose before the fifth day of exposure.

It goes without saying that in institutions such as hospitals, schools, orphan homes, etc., complete protection and not attenuation should be attempted. Usually a few attenuated or even complete attacks will occur even under these conditions, reexposing the others or newcomers. Since passive immunity persists for only about two weeks, individuals who cannot be removed from the infectious environment should be reinjected every two weeks during the period of exposure and every newcomer should receive serum. This procedure is innocuous, sensitivity not being caused by even repeated injections of homologous human serum, and, in our experience, reactions did not result from the use of properly prepared serum. In this way a hospital ward, for example, can be kept open continuously, and new patients admitted with almost negligible risk. Pooled adult normal serum will accomplish practically the same results as those just described, but it must be given in four times the amount. Pooled serum is more efficacious than serum or whole blood from one individual, such as a parent, because the pooling of many serums (usually 30) insures securing the immune principle which may be missing in a single serum.

Convalescent measles serum is potent when obtained as early as the tenth day after the beginning of the illness, provided the patient has been fever free for at least seven days. It is similarly potent when obtained as long as four months after recovery, and perhaps longer. The determination of how long a recovered individual will yield efficacious serum needs accurate determination. The longer the period, the larger can be the supply of serum, for each recovered adult or large adolescent can supply, with no risk, 250 c.c. of blood (yielding about 110 c.c. of serum) every two or three weeks for a period of six or eight months. In fact, their red blood corpuscles and hemoglobin usually increase, and polycythemia should be guarded against by blood counts before each bleeding.

It is generally stated that convalescent serum is of no avail after the actual development of measles. However, there is sufficient evidence to indicate that some curative benefit can be secured and that this therapeutic use should be reinvestigated. It may be that larger therapeutic doses should be given than have been used, and perhaps the limited supply, in the past, has prevented the administration of large enough amounts of convalescent serum.

SCARLET FEVER CONVALESCENT SERUM

The treatment of scarlet fever with convalescent serum was first practiced by Weisbecker in 1897. He used relatively small amounts of serum,

from 10 to 20 c c , but secured quite good results. A number of workers followed his example, but it was not until the advent of the Wassermann reaction gave security against accidental transmission of syphilis, that this study was pursued energetically. Larger amounts of serum were used (from 50 to 60 c c) with even more favorable results. The first trial in this country was by Zingher, in 1914, working with Park. Next followed work by Synnott (1917), another report by Zingher (1917) and one by Weaver (1918). Many reports since, in many countries, have shown the marked therapeutic value of pooled convalescent scarlet fever serum when this is given in large enough amounts and especially when administered intravenously early in the disease.¹ The beneficial results have been so definite that in article after article recommendations are made for the organization of agencies for collecting and distributing convalescent serum. Blood, yielding potent serum, can be drawn on the twentieth day after the onset of illness, provided the patient is convalescing and has been fever free for at least seven days, and further bleedings may be made at two or three week intervals for a period of four months and probably for as long as six months. About five years ago, with the cooperation of the Chicago Department of Health and of a number of colleagues, it was possible for me to organize the Samuel Deutsch Convalescent Serum Center at Michael Reese Hospital, and similarly a year ago the Milwaukee Convalescent Serum Center at Columbia Hospital. Some of the observations in Chicago have been published with Hoyne and Levinson.

Eight hundred and seventy-two children, giving no history of previous scarlet fever, and unavoidably exposed in their homes to this disease, were passively immunized with from 10 to 20 c c of pooled convalescent serum, and only 2.8 per cent developed scarlet fever. In similarly exposed home contacts, Park states that in his experience about 10 per cent contract scarlet fever, and Gordon's findings in Detroit were 15 per cent. Therefore, one can conclude that only one out of the expected four or six developed the disease. Stated in another way, convalescent serum protected from 75 to 83 per cent of those who without passive immunization would have contracted scarlet fever. Besides this, those who came down with this illness usually had it in a mild and modified form. In 83 Dick-positive hospital contacts, similarly immunized, only 5 per cent had scarlet fever. Because of the less direct nature of hospital exposure, this result is more difficult to evaluate.

The results of therapy have been published for 947 severely ill hospitalized patients and 983 home treated patients of varying degrees of severity, 1930 patients in all. The hospitalized patients were treated in the Chicago Municipal Contagious Disease Hospital under the direction of Dr. Hoyne. Only severely sick patients received serum, usually on admission, and 6,282 mildly or moderately ill patients, admitted to the hos-

* For complete review of the literature through 1930, see *Annals of the Pickett-Thomson Research Laboratory*, Vol. VI.

pital during the same period, treated symptomatically and not receiving serum, served as controls

Some of the findings can be briefly restated. Patients without septic complications showed an average fall of temperature of two and a half degrees in the first 24 hours and a total of three degrees in the first 48 hours when they received the convalescent serum within the first three days of their illness. Not infrequently there was a dramatic reduction of four to five degrees. When the serum was given from the fourth to sixth days of the disease the temperature drop was from one-half to one degree less. With the decline of temperature there was a corresponding and marked diminution of toxicity, fading or disappearance of the rash, relief from angina, nausea and vomiting, return of appetite, and shortening of the period of illness. Most patients with complications on admission or mildly ill but later developing complications were also benefited by serum but to a less degree.

The evidence definitely shows also that severely ill, serum treated individuals developed a smaller number of less severe complications than the mildly or moderately ill in the control group not receiving serum.

The dosage, depending on the size of the individual and the severity of the illness, varied from 40 to 100 c c. It was administered intravenously and occasionally had to be repeated. In the entire series no reactions occurred other than a few instances of mild urticaria. Intravenous administration is preferred to intramuscular injection because of rapidity of action and absence of reactions.

It may be of interest to note that excellent results have been observed by ourselves and others in the treatment with convalescent scarlet fever serum of various types of severe infection with hemolytic streptococci. Some of these results have been analyzed in a publication with Levinson. This would appear to be a profitable field of therapy and of further investigation. Immuno-transfusion, using adults recently recovered from scarlet fever as donors, has yielded some excellent results in very toxic patients with scarlet fever and also with various kinds of hemolytic streptococcus infections. This is a therapeutic agent which should have a wider use.

OTHER TYPES OF CONVALESCENT SERUM

More extensive investigation is much needed in the varied and important group of infectious diseases, especially as many small studies have yielded hopeful findings. Some of the convalescent serums referred to are for pertussis, pneumonia, typhoid fever, for vaccinia encephalitis, for complication of mumps, etc. Time will not permit presenting any tentative deductions from the literature or from personal experience.

SUMMARY

It seems clear that some convalescent serums, especially those for measles and for scarlet fever, having been demonstrated to have a consider-

able degree of usefulness, should be made generally available by the development of centers organized for their collection and distribution

These organizations also should be centers of investigation and research, under rigorously controlled plans, and should extend our knowledge not only of the value of convalescent serums for all infectious diseases but also of many fundamental immunological problems

THE VALUE OF CERTAIN DIAGNOSTIC PROCEDURES IN BRONCHOPNEUMONIA: A CLINICAL STUDY^{*}

By JOHN V FOPEANO, A B , M D , *Ann Arbor, Michigan*

IN a day when clinicians depend much upon the clinical laboratory for guidance in diagnosis and prognosis, there is a need for data showing the limitations of the objective methods of the laboratory. Even the reliable clinical thermometer may sometimes lead one astray.

In a study of the cases of pneumonia which have occurred during the past two years among students at the University of Michigan, three things have stood out clearly:

- 1 Absence of leukocytosis in uncomplicated bronchopneumonia indicates neither a good nor a bad prognosis

- 2 It is possible and not uncommon to have bronchopneumonia without any detected fever

- 3 The clinical diagnosis of bronchopneumonia and even of lobar pneumonia can sometimes be made two days before roentgen-ray confirmation is possible

The records of 62 cases of pneumonia occurring during the past two years contained roentgen-ray studies, clinical records, and laboratory work, sufficient for use in this study.

All of the cases except one occurred in students at the University of Michigan, and in young adults who for the most part were without any important complicating physical defects. The one non-student was a staff member aged twenty-eight. All cases were hospitalized in the Infirmary of the Health Service. None of the cases received vaccine or serum treatment. The treatment was symptomatic, consisting of strict bed rest, special nursing care in the more severe cases, sedatives, high vitamin soft diets, and nearly always acetylsalicylic acid during the period of acute illness. There were no deaths. The cases occurred during the period of September 1933 to June 1935. The roentgen-ray films were read by the Department of Roentgenology of the University of Michigan Hospital. In each instance the case was followed with roentgen-ray until clearing was complete. No other diagnosis than pneumonia appeared reasonable.

NO SIGNIFICANT RELATIONSHIP BETWEEN LEUKOCYTE COUNT AND THE SEVERITY OF THE DISEASE

In describing bronchopneumonia textbooks on medicine nearly always point out the presence of leukocytosis. The absence of leukocytosis is interpreted as being either a bad prognostic sign, indicating the lack of resistance,

^{*} Received for publication December 14, 1935
University of Michigan Health Service

or as the concomitant of a very mild infection. Even cases of influenza, normally having a leukopenia, are said to develop a leukocytosis when pneumonia appears as a complication if the resistance is good.

Early in our experience we were worried by the fact that cases of pneumonia so often failed to show a good leukocytic response. Later the frequency of low counts associated with a mild course of the disease led to a disregard of the white blood cell count and the number of polymorphonuclear neutrophilic leukocytes as indicators of the prognosis in pneumonia. These are still found useful as very early indicators of the development of complications.

In order to present this study of pneumonia in a graphic and mathematical manner, the severity of the disease has been expressed in terms of mortality, duration of fever, duration of hospitalization, and incidence of complications. All the cases were mild in the sense that there was no mortality.

The white blood cell count on the day of the highest fever has been used, since that is the time when the patient is usually considered sickest and it is then that the doctor is looking for a sign which will help to indicate the prognosis.

Chart 1 shows the height of the total white blood cell count on the day when the fever was at its highest point, plotted to show the duration of the fever in days. Chart 2 shows the total white blood cell count on the day of highest fever and the length of hospitalization.

A little study of the scatter maps, or statistical handling of the data they represent, reveals that about half of our cases have counts under 10,000 at the height of their fever, and that on the average the cases with higher leukocyte counts have no shorter or longer duration of fever or of hospitalization than those cases having no leukocytosis. There does, however, seem to be an increase in the incidence of complications in those who have low counts at the height of their fever. Seven complications occurred among 32 cases having counts of 10,000 or below, whereas complications occurred only twice in the 30 cases having counts of more than 10,000 at the height of their fever. The number of cases having complications is too small to permit any conclusions, because such a distribution of the white blood cell counts in a small series could quite often occur by chance. All of the cases developing complications showed a moderate to marked leukocytosis coincident with the development of the complication.

Handling these data in a way to show the standard error of the difference between the two variants reveals no significant correlation.

Another study (charts 3 and 4) was made, using the number of polymorphonuclear leukocytes instead of the total white blood count. This likewise showed no significant relationship between the height of the count on the day of highest fever and the duration of the fever or the length of hospitalization.

CHART 1 Pneumonia in University Students. Relationship between the total leukocyte count on the day of the highest fever and the duration of the fever in days. Dots represent cases

THE HEIGHT OF THE WHITE BLOOD COUNT AND THE ETIOLOGIC AGENT OF PNEUMONIA

In only 25 of the cases was successful isolation of an organism from the sputum accomplished. The organisms found were Pneumococci Types I, II, and IV, Pneumococcus type undetermined, *Micrococcus catarrhalis*,

CHART 2 Pneumonia in University Students Relationship between total leukocyte count at the time of the highest fever and the duration of hospitalization in days. Dots represent cases and those surrounded by a circle indicate cases in which complications developed. All of these cases having complications developed moderate leukocytosis with the onset of complications.

Streptococcus viridans, non-hemolytic streptococcus, *Staphylococcus aureus*, and gram-positive cocci unidentified. There was no significant relationship between the type of organism and the blood counts. However, the number of cases is much too small to permit any definite conclusions regarding a correlation between white blood count and type of organism recovered in the sputum.

CHART 3 Pneumonia in University Students Relationship between the polymorphonuclear neutrophilic leukocyte count on the day of highest fever and the duration of fever in days Dots represent cases

THE HEIGHT OF THE WHITE BLOOD COUNT AND THE KIND OF PNEUMONIA

Only five of the 62 cases were diagnosed as lobar pneumonia. In these five cases the polymorphonuclear count at the height of the fever varied from 4,000 to 14,000, and here again there was no relationship between the height of the white blood cell count and the duration of the fever or hospitalization.

CHART 4 Pneumonia in University Students. Relationship between the polymorphonuclear neutrophilic leukocyte count at the time of highest fever and the duration of hospitalization in days. Dots represent cases.

PNEUMONIA WITHOUT FEVER

Six patients had no fever during the period of hospitalization. These afebrile patients were examined by roentgen-ray because they had physical signs (râles) or symptoms such as cough, general malaise, or pain in the chest. The diagnosis was made by means of roentgen-ray and the sub-

sequent behavior of the shadow allowed no other interpretation of the films. The shortest period of hospitalization was six days and the longest fourteen. The period of hospitalization was determined by the length of time necessary for complete disappearance of roentgenographic shadow. None of these cases had any complications. Three of the cases had white blood cell counts which remained below 8,000 and three had blood counts between 10,000 and 12,000. The causative agent in four cases was not determined due to lack of sputum and the mildness of clinical symptoms. In one case a pneumococcus (type unknown) was obtained and in another a mixture of *Micrococcus catenulatus*, *Staphylococcus albus*, and non-hemolytic streptococcus. All were reported as bronchopneumonia involving a single lobe.

CLINICAL PNEUMONIA WITH DELAYED APPEARANCE OF ROENTGEN-RAY FINDINGS

In this series there have appeared eight cases in which a clinical diagnosis of pneumonia was made but which had negative roentgenograms until after the third day. Two of these cases had lobar pneumonia and six broncho- or lobular pneumonia. All of them were confirmed when roentgen-ray films were made on the third to the ninth days. *In the same breath it must be emphasized* that in many instances pneumonia was not diagnosed until the Department of Roentgenology made its report.

CONCLUSIONS

Conclusions derived from this study of 62 cases of pneumonia in University students are as follows:

- 1 White blood cell counts between 6,000 and 35,000 and total polymorphonuclear neutrophile counts between 4,000 and 30,000 when the temperature is highest, are not indices of the prognosis as to duration of fever or hospitalization, or as to complications.

- 2 The height of the leukocyte response does not appear to be determined by the kind of organism recovered from the sputum or by the lobe involved. The number of cases of multilobar involvement and lobar pneumonia encountered is too small to permit conclusions, but it is not uncommon to have low counts even in lobar pneumonia.

- 3 It is possible and fairly common to have bronchopneumonia without any detected fever.

- 4 The clinical diagnosis of bronchopneumonia and even of lobar pneumonia can be made sometimes two days before roentgen-ray confirmation is possible.

- 5 It is a very common experience to have roentgen-ray evidence of bronchopneumonia without clinical signs of the disease.

WHAT THE PHYSICIAN SHOULD KNOW ABOUT DENTAL PROBLEMS¹

By WM J KERR, M D , F A C P , *San Francisco, California*

IT is indeed an auspicious occasion which brings together the dentist and the physician. They have too long traveled independent courses to the detriment of each. The schism which led to the development of modern dentistry is so recent that most of us can recall the family doctor who practiced dentistry as a "side line". His efforts were directed chiefly toward the relief of pain in an aching tooth. When he failed in this, the ever ready forceps in his medical kit came into action. The village blacksmith was also handy with his tongs or with the punch and a well directed blow of the hammer. I must confess to personal transgressions upon the province of the dentist when, a few years ago as a ship's doctor, I was obliged to remove two remarkably loose teeth from the mouth of a wayfare. This was done to prevent him from aspirating them during sleep. My activity in the dental field, however, has been confined chiefly to the timely plucking of deciduous teeth from our four children with due foresight to cooperate with the fairies and place a quarter of a dollar under the pillow at night as a reward for the sacrificed tooth. We have done our share to support the manufacturers of tooth-brushes and dentifrices and to inculcate from birth good habits for the proper care of the teeth. We have also tried to provide the elements of diet which aided in the development of the teeth and jaws and their preservation. These efforts have not met with favor by the youngsters but have been taken on faith. The periodic visits to the dentist have revealed our shortcomings and after frequent repairs the outgoings from the purse have been considerable. However, we have preserved full dentures with satisfactory function. For ourselves and our parents we have striven to preserve what was left of our permanent teeth after a poor start in childhood, and have replaced the missing members which have been sacrificed upon the altars of negligence and time. We have, no doubt, leaned heavily on our dentist for restoration of function but, certainly, we must confess to some solicitude for looks and the enjoyment of a savory bolus, well chewed. We must also confess to frequent surprises when our dentist reminded us that it was past time for a visit to his office to look over the "tombstones". This sounded like business for the dentist and one wondered at his trustful nature when we had just finished paying for the last visits.

Having detailed a few personal experiences and confessions, it may be proper to ask what the average physician knows about dental problems. In the first place he knows about what the average citizen knows, or a little

¹ Read before the Pacific Coast Dental Conference, July 1935. Received for publication April 25, 1936.

From the Dept of Medicine, University of California Medical School, San Francisco

more If he hasn't been out of medical school too long, he knows something about the development of the teeth from his course in embryology His knowledge of the anatomy or structure of the teeth is sketchy and his acquaintance with the diseases of the teeth is gained through a reversed perspective in the examination of the mouth in his patients He is obliged to learn the dates for the eruption of the deciduous teeth for anxious young mothers, subject always to correction by experienced grandmothers He has a passing knowledge of gross changes shown by roentgen-ray films—often poorly taken

The average physician pays scant attention to the teeth and other parts of the organ of mastication unless they are seriously and obviously diseased He knows that in certain instances the teeth and adjacent structures may act as foci of infection, in fact, he has been too enthusiastic on this point during the last generation The result has been the wholesale sacrifice of doubtfully offending and often of sound teeth The physician has been too ready to advise extraction of teeth without a thought to the limits of the dentist in restoration This practice, urged by well meaning physicians who saw only one side of the shield, has happily been limited in recent years under the influence of dentists of better training who look upon the tooth as a living organ Physicians, also, have learned more about the value of methods of body-building which favor the control of local processes At a higher level of general well-being the small foci of disturbance are controlled and are no longer a menace to health

Current medical literature is filled with discussions on metabolic disturbances, disorders of the endocrines, and the action of the vitamins, which may affect the integrity of the teeth and contiguous structures The physician and likewise the dentist are intrigued by the prospects Unfortunately, fancy too often overruns the facts The sins which are committed in these fields of therapeutics are numerous and, until we have more accurate scientific information, the chief beneficiaries are the pharmaceutical houses, which put up their products in such delectable forms and at fancy prices

The public is conscious of the great achievements in science They eagerly and innocently accept the pseudoscientific statements blazoned forth in advertisements of nostrums and "curealls" Both medical and dental practitioners have lent their names, unfortunately, sometimes inadvertently but usually for gain, to this class of propaganda They would have us believe that oral antiseptics really have some value and that some particular dentifrice is superior to all others when it is the peculiar odor, flavor or color which we enjoy They play upon our fastidious natures since we wish to be socially acceptable It is high time that we take the leadership in this matter The public should look to the dentist and physician to keep abreast of scientific knowledge and to give advice in all matters pertaining to health

An increasing number of physicians are interested in dental problems. The general practitioners and specialists of sorts in every branch of medicine. They and those who limit their practice to certain fields, the specialists, are busily checking their clinical experience against the discoveries in the experimental laboratory. The more forward dentists are, likewise, interested in the problems and in many directions have actually assumed leadership. Their interest arises naturally from a desire to seek the causes for the diseases and conditions which they are called upon to treat. They do not wish to become general practitioners of medicine but they rightfully insist upon recognition as specialists in medicine. The technical procedures employed in dentistry require special knowledge and training but the future field of the dentist does not end there.

We may now ask what the physician should know about dental problems. Naturally, he is not concerned with technical procedures unless they directly affect the general health of the patient. Certain dangers may be encountered if in the execution of dental care poisonous substances are used, unsafe or ill advised anesthetics may be employed in a given case, or infection may be introduced.

The physician should know that the teeth and supporting and sustaining structures are living parts of the body and deserve due respect. They are capable of growth and repair, and die when not properly nourished. They may be injured or destroyed by accident, disuse, disease or faulty care.

The teeth are most important parts of the organ of mastication. They operate in a systematic manner to prepare the food on its route to the digestive tract where more intricate functions are performed. When one comprehends the manner in which the jaws, muscles, cheeks, lips, tongue, salivary glands, and the teeth cooperate to handle the bolus of food, he can understand the enthusiasm which led to Fletcherism of by-gone days. One can live on foods which do not require mastication, but so can people live without stomachs and with a large part of the bowel removed, but none would agree that these individuals are properly nourished.

The modern tendency to use prepared and predigested foods is, no doubt, giving rise to faulty development of the face, jaws and teeth through lack of use. The "rugged individualism" in which most Americans take pride will not apply to their powers of mastication. The pap which is served from the cradle to the grave will make of us a race of facial weaklings.

There can be no doubt that heredity influences the organs of mastication. The shapes of jaws, the configuration of the teeth, their number and positions are modified through such factors. The quality of teeth likewise appears to be inherited, but it is possible that habits of eating and quality and quantity of food in a family group are the factors which operate and are mistaken for the influence of heredity in such cases. At present we can do nothing to control hereditary factors except in those diseases like hemophilia where known bleeders can be prevented from begetting offspring. There is a rare inheritable disease known as dysostosis-cleido-cranialis, which is due

to a disturbance in the formation of bone in the sixth week of intrauterine life and just before the teeth begin to form. In such cases the skull is improperly formed, the development of the teeth and jaws is retarded and never becomes normal, the clavicle is frequently present in only the central portion and other membranous bones are imperfectly formed. At present there is no known way to prevent this disease, which may occur in several generations, except by contraceptive measures.

There are a number of congenital diseases which are known to influence the teeth and buccal tissues. Chief among these is syphilis which distorts the palate, gives rise to imperfect formation of teeth and to scarring of the lips. This misfortune is preventable and the means are in the hands of the physician who cares for the parents. Among the metabolic diseases are rickets and cretinism where preventive measures during pregnancy may correct the defects in the growing fetus, in the first instance by the administration of adequate calcium, phosphorus and vitamin D, and in the other by the use of iodine or thyroid extract by the expectant mother.

At the time of birth the well trained obstetrician should know that injuries to the jaw and facial nerve may result from faulty application of forceps, which may lead to abnormal mastication later in life.

The physician should know that the teeth are formed early in the life-history of the individual and that prenatal and early post-natal influences are most important for proper growth. It appears to be well accepted that breast fed babies have better teeth than those fed on a bottle. Infants should have something to masticate as soon as they have the tools to do so and probably require something firmer than milk to aid in the proper development of the jaws and the eruption of teeth. If a greater variety of food-stuffs were offered to infants during the young robin age, perhaps when they are older, children wouldn't be so particular about things we think are good for them—even spinach. Most liquid diets or pappy diets served to infants and young children are relatively inadequate in certain particulars. Human milk from healthy mothers is the most perfect food for the new-born child.

Physicians and mothers should know that if an infant sleeps constantly on the face or on its hand, the bony structures of the face may be deformed, resulting in defective support for the teeth. Thumb sucking may likewise deform the palate and other structures.

As the child becomes older, there are increasing demands for substances which promote growth until the great epoch of puberty, when such processes are at their height. In the osseous structures, including the teeth, there is need for minerals and chief among these are calcium and phosphorus. There must be adequate supplies of other extrinsic factors such as growth-promoting vitamins. The internal organs which provide for the digestion, absorption, elaboration and storage of these substances must be functioning properly. The ductless glands, especially the pituitary, thyroid and parathyroids, and perhaps the gonads, must be relatively normal if growth, with

its checks and balances, is to be favorable. The ravages of constitutional disease and the exanthemata may distort the normal progression of events and frequently do so, leaving mementos in the more permanent structures such as the bones and teeth.

It is at this stage of greatest growth when dental caries is encountered. The modern trend is to attribute such disorders to nutritional disturbances in a broad sense and perhaps to a decreasing extent to local and environmental conditions in the mouth. It may well be that both factors are operative. Far be it from me to take sides in a highly controversial field. The relative immunity of certain groups to dental caries would suggest that nutritional factors are important. The universal loss of most of the teeth early in life in certain sections of the British Isles led a young American soldier to a pointed remark during the World War. In speaking to a fellow soldier after a day of leave he remarked, "I have just kissed the prettiest girl in Scotland and she had a full set of teeth—one above and one below." It would appear reasonable to assure ourselves that growing children are supplied with all the known factors for adequate growth and development and at the same time to care for the teeth and their environment to the best of our ability.

We are just now emerging, we hope, from a period of great nutritional deprivation for many millions of our population. We have seen a few examples of nutritional diseases in an exaggerated form among them but how many are experiencing subclinical types of deficiency disease there is no sure way of knowing. It is likely that dental defects for many decades to come can be attributed to these years of undernutrition. It will be difficult to trace, however, in view of the long time required for the younger sufferers to reach maturity. Fortunately, those charged with the administration of relief have given some thought to balanced rations but where cash-relief has been given, most of the money has been used for the purchase of the cheapest food-stuffs, which are carbohydrates. The deductions for alcohol, tobacco, confections and cosmetics also limit the total funds available for purchase of essential food-stuffs.

A group that may benefit from the depression are those individuals who tend toward adiposity. Here the general health may be improved by restricting the diet, provided their ration is properly balanced.

There are certain constitutional disorders which give rise to local disturbances in the mouth and teeth. We are well aware of the spongy gums of the patient with scurvy (due to lack of vitamin C) and the historical accounts of sufferers from this disease in the olden days of discovery are familiar to all. Happily we see few outspoken cases today where teeth loosen and fall out, but mild scurvy may exist among our undernourished population. The dentist may be the first to encounter this condition.

The relationship between rickets and deficiency of vitamin D is well known. We recognize the importance of adequate intake of calcium and phosphorus, ultraviolet light, and normally functioning parathyroid glands.

in the growth and deposition of bone. Recently we have learned that bile salts must be excreted with the bile to permit vitamin D to pass into the system. The pregnant woman has unusual demands for materials to build the skeleton and teeth of the fetus, and in experimental studies the pregnant animal actually shows a negative balance for calcium unless it is supplied in abundance and other factors are harmonious. The penalty for pregnancy is destruction of teeth in the mother. If supplies for the growing fetus are inadequate, the infant suffers, also, throughout the osseous structure and this lack often appears in defective development of jaws and teeth. Rickets and scurvy are but two of the deficiency diseases which give rise to dental problems. Deficiencies in vitamin A, which appear to be important in preserving epithelial structures, may give rise to dental defects but our present information is inadequate on this point.

Diseases of the ductless glands no doubt are important in causing defects in the jaws and teeth but our present knowledge about them is rather chaotic. Over-production of the growth-hormone after puberty certainly distorts the jaws and leads to malocclusions and separation of the teeth with other disturbances in growth of the local tissues. Hypofunction of the pituitary (Simmond's disease) may result in underdevelopment of the organs of mastication or a regression of local tissues in general. Hypo-thyroidism is a potent factor for underdevelopment in utero and in childhood but less significant in adult life when secondary changes may be caused by underfunction of the thyroid. The parathyroid glands may, rarely, become hyperplastic or may be the site of adenomas which cause hyperfunction. This disturbance leads to cyst formation and general fibrosis in the bones, and in this process the jaws may share. We have seen a number of such cases in the past few years.

All constitutional diseases which lower the general vitality may affect the jaws, gums and teeth and interfere with their proper nourishment. Local lesions may also occur. Tuberculosis and syphilis are examples of this type, the latter especially exhibiting destructive processes in the palatal and facial bones.

The heavy metals, entering the body by accident or intent as therapeutic agents, are frequent causes of destructive lesions in the supporting structures for the teeth. Mercury is notorious for its action in causing salivation and the loosening of teeth. Lead, bismuth and copper likewise cause local changes and are deposited in the margins of the gums in untidy mouths. Radium and other radioactive substances are dangerous to the bones of the jaws and other local tissues, as we have learned from the experiences of workers in factories where dials are marked with illuminated paints. In such work the brushes are kept pointed by frequent contact with the lips. Arsenic, when applied locally, may cause necrosis of local structures and lead to chronic ulcerations. Iron is frequently used in the treatment of anemia and it is well known that local discolorations of the teeth may result. This is apparently not due to contact with the teeth in taking the drug but enters by way of the circulation.

The elements phosphorus and fluorine have interesting effects on bones. Fortunately, phosphorus has ceased to be a frequent cause of necrosis of the jaw since its use in certain compounds has been prohibited in the manufacture of matches. Fluorine, the salts of which are among the most soluble substances known, is a normal ingredient of teeth. When ingested in excess, however, marked overgrowth of periosteum and deposition of collars of bone occur outside of the normal bone. Such overgrowths may be seen in the jaws and peculiar mottling of enamel may be noted. These defects occur in districts where the content of fluorine in the drinking water is high. Water containing more than 1 milligram per cent is considered unsafe for drinking purposes. The malady affects the enamel during the preeruptive period. At present there is no known way to remove excessive amounts of fluorine from the water and some other source of potable water must be found. We should be extremely cautious in choosing a water-supply from certain regions of the Rocky Mountains.

Mention has already been made of hereditary bleeders, or hemophiliacs. It is common knowledge that the royal families of Spain and Russia were afflicted with this disease. The physician should know the dangers of fatal hemorrhage resulting from the extraction of teeth in such cases and should cooperate with the dentist if necessary technical work is to be done.

A disease of the blood and blood-forming organs, known as leukemia, frequently manifests itself first in the gums with hemorrhage. The dentist may be called upon to treat the local condition. The physician attending such patients should warn the dentist in advance of the dangers of radical treatment of the gums and teeth until this fatal disease is under temporary control.

Cancer and sarcoma may arise in the lips, gums, teeth, jaws or other structures in the mouth and interfere with the function of mastication. The physician, in such cases, usually looks upon the dental problem as a secondary one in view of the rapidly fatal course of the disease. However, in some protracted cases and especially if destructive operations are necessary, the active cooperation of the dentist is imperative.

In fractures of the jaw the problems of early approximation of fragments, the realignment of teeth, and prevention of infection are of major importance. Here is the opportunity for real intelligent teamwork between the physician and dentist. Often in complicated cases extractions are necessary and reconstructions are useful.

We now come to a brief discussion of focal infection. There can be no doubt that focal infection in the mouth and elsewhere may give rise to serious constitutional disease. From the writings of Hippocrates, Dryden,* Benjamin Rush and Billings and his followers, we have become

* Dryden, "The throttling quinsy 'tis my star appoints,

And rheumatisms descend to wrack my joints"—Suggestion from Dryden before the year 1700, showing connection between focal infection (quinsy) and rheumatism. Mentioned by Dr. M. H. Dawson.

aware of their frequent association. That the practice of wholesale removal of teeth for suspected foci has been overdone needs no emphasis before this group. I have already mentioned the observations indicating that local lack of vitality may result from constitutional disease. There can be no argument with those who wish to remove a proved focus of infection for its own sake but in practice we have too often mistaken the cart for the horse. In any group of debilitated people we will find many who show several foci of infection and these local lesions are not limited to the teeth and surrounding structures. If we can build up these patients generally, the local processes will usually become insignificant.

The problem of pyorrhea alveolaris or, to use the more non-committal term, paradentosis, is still unsolved. How much of a rôle infection plays as a primary factor is undetermined. There is no doubt that infection may localize in the tooth and around the tooth, may extend to the soft tissues, and may penetrate the bones themselves. The physician who may see the patient first should be aware of the dangers of untreated infection and secure the advice and cooperation of the dentist at the earliest possible moment. It has been my experience, on a number of occasions, to hear of some patient with osteomyelitis of the jaw who sustained a fracture during the extraction of a tooth. The explanation is that the patient usually goes to the dentist for "tooth-ache" and if proper roentgen-ray films are not made, the involvement of the mandible is not revealed. It is the duty of the physician to know that in such cases the mandible is riddled with osteomyelitis from the time first seen, and that such results come from neglect of infected teeth or alveolar processes. The dentist is rarely to blame for such fractures. The destruction and deformity resulting from osteomyelitis of the jaw are frequently extreme and a satisfactory outcome is a credit to medico-dental cooperation.

Actinomycosis of the jaw is an infectious disease rarely seen in man. The problem is a difficult one and the results may be unsatisfactory.

Vincent's infection interests both physician and dentist. Too often the physician fails to recognize or treat properly the local infection in the mouth. The well trained dentist should be asked to cooperate. General measures may also be necessary and require the assistance of the physician.

Chronic atrophic or deforming arthritis and dental infection are frequently linked in our treatises. After many years of enthusiasm and frequent disappointment, the best medical viewpoint has shifted toward conservatism. If bacteria are agents in the cause of the arthritis, no one organism has been shown to be specific. We are now seeking more general or endogenous causes for this disease. Recently a deficiency of vitamin C has been suggested and this may well be a factor in causing the changes in the joints and in the periodontal tissues resembling mild scurvy. Further study will be needed to solve these problems.

In the foregoing remarks I have tried to show a few of the diseases encountered by the physician which introduce dental problems. With these, at

least, the physician should be familiar. From the numerous studies being undertaken in clinics and laboratories will come light upon the solution of the many problems which vex us. It is to be regretted that workers in the medical sciences have neglected a most important part of the body. Fortunately, those few whose training has been along dental lines are making notable contributions in this field. When physicians recognize the importance of the organ of mastication for the welfare of the body as a whole, there will be further contributions from the medical profession.

This brings me to my closing remarks which pertain to the future of dentistry. It is inevitable that the training of dentists will begin on a wider basis of scientific education. The preclinical sciences, as organized in the medical schools, will be prescribed with such training in the clinical branches as may be required to acquaint the student with man as a biological unit. His deviations from the normal which constitute disease will demonstrate the man out of health. The great field of preventive medicine will be unfolded for the dental student. The technical procedures which are required will be developed along the way but his mastery of them will come after his biological concepts are well grounded. Dentistry will then become more than a craft. The dentist will be, in fact, a specialist in medicine and on an equal footing with other medical specialists. The changes now going on in the dental schools of this country are healthy signs of a new order. All forward looking physicians should be ready to give encouragement and active support. What the country needs is not more physicians and dentists but better ones. We must cooperate to set high standards of professional attainment. We must harness science to our uses in the practice of our art. The resources of knowledge are almost unlimited. Anyone who is observant today knows that the discoveries of the future will dwarf those of the past. May the dental profession share in these epoch-making contributions.

CASE REPORTS

A CASE OF DIAPHRAGMATIC HERNIA IN WHICH MARKED CYANOSIS AND DYSPNEA WERE THE PRE-DOMINATING SYMPTOMS

By HENRY F STOLL, M D , F A C P , *Hartford, Connecticut*

IT is of more value to the clinician to be acquainted with the varied clinical pictures which may be caused by a diaphragmatic hernia than to be fully informed as to the details of its anatomical features, or as to the various proposed classifications of diaphragmatic defects. In the instance to be reported, the presenting symptoms and signs were unusually misleading, and it is from this point of view that the case seems worthy of record.

E V, female, aged 50 years, was admitted to the Hartford Hospital on May 9, 1935, and died on May 10, 1935.

Chief Complaint Shortness of breath

Present Illness Prior to one month ago the patient apparently had been in excellent health. At that time she began to have some dyspnea on exertion. She minimized her symptoms, and the family was not alarmed until about a week before admission when the skin began to have a dusky color. She refused to have a doctor called until just before admission, as she claimed she "felt well." However, a slight edema of the ankles was noted for the last two weeks of her illness and she also had a slight cough. There had been no nausea, vomiting or any complaint of pain though she had taken only liquid for a few days prior to admission.

Physical Examination Fairly well-developed and nourished woman with extreme cyanosis suggesting somewhat chronic acetanilid poisoning. There was no adenopathy or thyroid enlargement present. Respiratory excursion of the left chest was almost entirely absent. Over the lower two-thirds of the left chest anteriorly and posteriorly there was a flatness with absent voice and breath sounds. One observer detected a small area of tympany over the left apex on percussion. Over the right chest the breath sounds were very much exaggerated and there were moist râles throughout the lower half. Heart was displaced markedly to the right. Rhythm regular. Sounds were of "tick-tack" quality. No murmurs heard. Blood pressure on admission was 190 systolic and 88 diastolic, subsequently it was found to be 135 systolic and 80 diastolic. Spleen not felt. No demonstrable fluid wave in the abdomen. There was considerable edema of the lower extremities.

Urine specific gravity 1.014, albumin plus 3, numerous hyalin and granular casts.

Subsequent Course Four unsuccessful attempts at thoracentesis in various areas were made, only 5 cc of thin, blood-tinged fluid being obtained. The patient was immediately put in an oxygen tent with considerable temporary improvement in the cyanosis. Pulse was of good quality, 92 to 104. Respirations were rapid and shallow. Notwithstanding stimulation, the patient died about 30 hours after admission.

* Received for publication November 13, 1935

The cyanosis and dyspnea were so extreme that before making an examination, one wondered if one were dealing with a case of Ayeiza's disease. However, the physical signs seemed conclusive of massive hydrothorax. The patient's age and the relatively insidious onset seemed to favor an effusion associated with a malignant growth, though an effusion of tuberculous nature and a hydrothorax from cardiac failure were also considered. Our impression, however, was that the cardiac failure was not primary. The roentgen-ray

FIG 1

films were a good deal of a surprise in that they did not show as much fluid as the degree and extent of dullness suggested but they revealed a large amount of air which could not be demonstrated by physical examination. The conclusions of the Roentgenological Department were "A left-sided hydropneumothorax with evidence of old fibrotic infiltrative changes in and adjacent to the right hilum together with arteriosclerotic changes in the aortic arch."

The note of Dr. Morris T. Root, who examined the patient with me shortly

after admission, expresses our confusion "Even after seeing the roentgen-ray, I was unable to elicit resonance over the upper part of the chest where air was reported, also I could not elicit succussion sounds. These facts, with the absence of fluid in chest tap, I was totally unable to account for"

Notwithstanding the fact that the previous health of the patient was stated to have been good, it was felt by most of those who saw her that there was probably a malignancy present with mediastinal involvement and some unusual

FIG 2

FIGS 1 and 2 Both the postero-anterior and lateral views show air and fluid within the left pleural cavity and marked displacement of the heart to the right. The air is within the stomach and the fluid is the gastric and intestinal contents. The spleen and pancreas contribute to make the dense shadow below. There is also a suggestion of old infiltration at the hilus of the right lung. The right lower lobe appears partially atelectatic.

thickening of the pleura which prevented the fluid from being obtained and the usual signs of hydropneumothorax from being elicited Yet no one felt at all sure as to what was the underlying cause

Immediately following death, the house physician, who was much disturbed by his failure to obtain fluid, made further attempts Thinking he had previously not gone low enough, he introduced the needle first into the ninth interspace, two inches from the spine, and obtained about 400 c.c. of cloudy, cafe-

FIG 3 After removal of omentum stomach seen occupying the upper part of the left thoracic cavity, with colon below Note very small amount of lung (right), the left lung is completely collapsed

au-lait colored fluid which became thick and muddy resembling liquid feces though having no odor A second tap made anteriorly produced fluid very similar but with a definite odor of gastric contents A third tap made in the second interspace anteriorly yielded 100 c.c. air (He thought that in going so low he had introduced the needle below the level of the diaphragm into the stomach anteriorly and the large bowel posteriorly)

Postmortem Examination The autopsy summary performed by Dr Perry Hough was as follows "*General Description* There are many recent needle scars in the left chest anteriorly and posteriorly There is a two plus pitting of both legs On opening the thoracic cavity the left pleural cavity is seen to contain the entire stomach, situated in the posterior half and apical region Overlying this there are about 50 cm of transverse and descending colon with attached omentum In the left lower portion of this pleural cavity is the spleen and a portion of the tail of the pancreas is likewise included These organs have entered the left pleural cavity through a defect in the left diaphragm measuring 17 by 12 cm The edges of this defect are smooth, firm and fibrous, apparently congenital No evidence of recent laceration The left lung is completely atelectatic and contains a scar in the region of the apex suggesting an old healed pulmonary tuberculosis The heart is entirely to the right of the midline, weighs 430 grams The pericardial fluid is not remarkable There is a definite hypertrophy of the right ventricular musculature measuring on the average 11 mm in thickness The left ventricle is 19 mm in thickness There is a two plus dilatation of both ventricular cavities The myocardium everywhere appears normal and the valves are competent *Pancreas* Is of normal size On section appears quite hemorrhagic, somewhat opaque This probably represents congestion The other abdominal viscera show no gross pathology *Right Lung* Weighs 460 grams as compared to the left weighing 120 grams There is compensatory hypertrophy, especially of the upper lobes and on section a two-plus congestion No inflammatory reaction present *Microscopical Autopsy* Kidneys, spleen, pancreas and liver all show a normal microscopical structure except for a two to three plus acute passive congestion *Lungs* Moderate congestion and edema Atelectasis of left lung Section from the apical region of the left lung shows dense fibrous scar tissue with nodular areas which contain amorphous calcium deposit suggesting an old healed pulmonary tuberculosis with no evidence of activity at present *Heart* Microscopically normal"

DISCUSSION

The actions of the heart, lungs and hematopoietic system are to a considerable degree reciprocal When the surface for gaseous exchange in the lungs is markedly cut down a compensation may be partially achieved by increasing the number of erythrocytes or by increasing the rate of blood flow through the lungs In time, this will cause ventricular hypertrophy and possibly dilation as occurred in the case here reported As the distention of the stomach and colon increased, the heart was pushed so far to the right that it compressed all but the right upper lobe

SUMMARY

A fifty-year-old woman who, as far as is known, had always been in good health, entered the hospital with severe cyanosis and dyspnea after an illness of only two weeks There were no symptoms referable to the gastrointestinal tract except that she had been taking only fluids prior to admission The physical signs were those of an enormous hydrothorax on the left with displacement of the mediastinum and contents to the right The inability to obtain fluid by thoracentesis during life was surprising in view of the marked flatness but readily explainable when the true condition was revealed The aspirating needle, gently introduced in the usual manner, pushed the thick-walled viscus ahead of it and only with a vigorous thrust, after death, was the wall penetrated

Autopsy showed diaphragmatic hernia (probably congenital) with the stomach, colon and spleen and tail of the pancreas occupying the left thoracic cavity Death was apparently due to over-distention of the stomach and colon with resultant extreme anoxemia and cardiac failure

HEREDITARY DYSTROPHY OF THE HAIR AND NAILS IN SIX GENERATIONS

By HENRY JOACHIM, M D , F A C P , *Brooklyn, N Y*

IN the August 1935 issue of the *American Journal of the Medical Sciences*, M E Hobbs, of Saint John, N B, Canada, reports a case of hereditary onychial dysplasia with a genealogical chart extending to four generations including 35 members, of whom 11 were affected. I have observed a case in which this condition was accompanied by alopecia which was traced through six generations

CASE REPORT

E S, female, 24, married, French Canadian, was admitted to the Cumberland Hospital on February 11, 1935, complaining of lower abdominal pain, dysmenorrhea and backache. Since birth there was an almost complete alopecia of the scalp with absence of axillary and pubic hair. This was accompanied by deformities of the finger- and toe-nails.

*Sumner - wd 40
2-9-35*

FIG 1 Dystrophy of the finger-nails. The tunnelling of the nails is shown.

Family history A similar condition is present in her grandmother, two great aunts and mother. The patient has five brothers and two sisters who are unaffected by this abnormality. Baldness and nail deformities are recorded in six generations originating in a woman (E C) who had 10 children, five of whom had this condition (four girls and one boy). In the third generation of 10 children, three girls and two boys were affected. In the fourth generation of nine children, four girls including the patient's mother (H D) and one boy suffered from this anomaly. In the fifth generation of 11 children, three girls, including the patient (E S), were affected. In the sixth generation of two children, one girl was recorded as having this condition. The patient's mother is an epileptic, and one brother who has normal hair and nail development is mentally defective.

Past history The patient's weight at birth was three pounds. The delivery was

normal As a child she had measles and pertussis She is subject to hives from fish and oysters Her menses began at the age of 13, they were of seven days' duration until her marriage four years ago after which they decreased to four days They have occurred every 28 days and have been accompanied by lower abdominal pain and backache She suffers from leukorrhea She is sexually frigid and submits to intercourse from a sense of duty She has been pregnant on two occasions The first pregnancy was artificially terminated and was followed by sepsis The second pregnancy ended in a miscarriage following a fall The patient is subject to severe pounding temporal headaches Her vision is poor, that of the left eye being blurred since childhood She suffers from dyspnea and palpitation on exertion and since her marriage is weak and easily fatigued She is habitually constipated Within the past year she has lost 10 pounds in weight, is nervous at times and flushes easily She has had thyroid medication

FIG 2 Dystrophy of the toe-nails

Physical examination Patient is well-nourished and of fair complexion The scalp reveals a generalized alopecia with a few fine hairs varying in length from one-eighth to four inches The eyebrows are practically absent, the eyelashes are sparse Exophthalmos is present, more marked in the left eye Her skin is dry except in the axillae and palms of the hands which are moistened by perspiration A few fine hairs are present on the lips and chin Breasts, heart and lungs are negative Pulse and temperature are normal The abdomen reveals no abnormalities Vaginal examination discloses a slight discharge, cervix moderately eroded, with a tender, walnut-sized, irregular mass to the right of the uterus This mass is diagnosed as a fibroid The finger-nails are pitted and arched and convexly lifted

from the nail bed causing a tunnel-like appearance. The toe-nails are atrophic and small.

Laboratory data Roentgen-ray of the skull revealed flattening of the floor of the sella turcica. The pelvic bones were negative. Blood Wassermann test was negative. The blood sugar was 90 mg on a fasting stomach, and after a glucose tolerance test it was reported as 151.5 mg at the end of one-half hour, 121.1 mg in one hour and 119 mg after two hours. Smears from the cervix were negative for gonococci. The basal metabolic rate was minus 31. Eye examination revealed a slight uniformly contracted visual field of the left eye. The blood pressure was 100 systolic and 60 diastolic. The urine showed occasional pus cells. Hemoglobin was 90 per cent, the red cells numbered 5,160,000, and the whites 9500 with 73 per cent of polynuclears.

Therapy Patient received five injections of antuitrin S, in doses of 1 c.c. subcutaneously. This treatment was discontinued because of pelvic pain which necessitated surgical intervention. A laparotomy was performed. A right tubo-ovarian abscess and a left hydrosalpinx were found at operation. Smears and cultures from the pus were bacteriologically sterile. Convalescence was uneventful. The patient was discharged from the hospital on March 31, completely recovered from her operation.

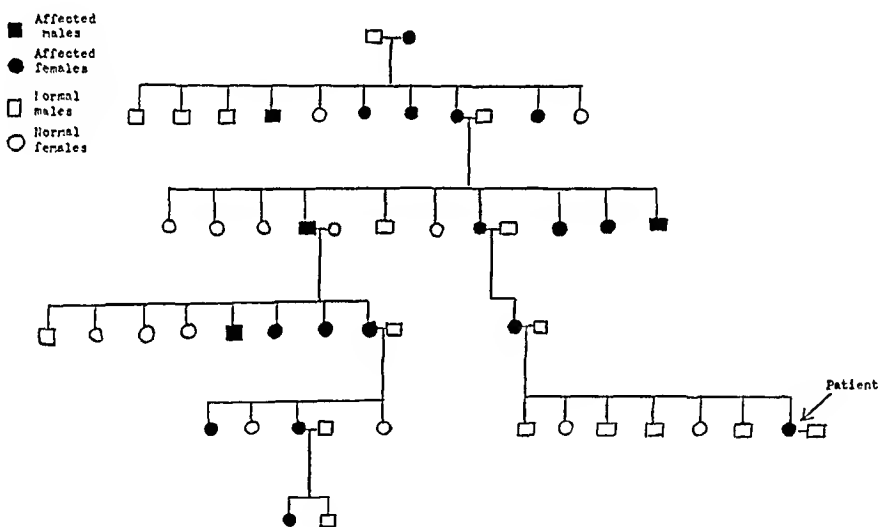

CHART I

The accompanying chart is a genealogy of the patient obtained from her mother who had in her possession a record of the family tree. No separate record is available to determine which of the cases were those of alopecia, nail deformity or both.

SUMMARY

A case of hereditary dystrophy of the hair and nails is presented. A chart is included showing the family tree of 43 members of her family with 19 suffering from this disease during a period covering six generations.

I wish to thank Dr. Walter F. Modrys, my former resident at Cumberland Hospital, for obtaining the family tree for me, and Dr. David Bellin, my present resident, for help in publishing this case.

THE NEPHROSIS SYNDROME ASSOCIATED WITH TERMINAL UREMIA

By PAUL H. WOSIKA, M.D., *Chicago, Illinois*

NUMEROUS cases of so-called "pure" "genuine" or "lipoid" nephrosis have been described in the literature. A close inspection of these reveals that very few cases in adults conform to the rigid rules clearly stated by Leiter¹ in his review of the subject in 1931. Using the clinical criteria mentioned as necessary to establish the diagnosis, several authors have published reports of groups of cases of nephrosis, whereas other authors equally interested in the problem of renal disease state that true "lipoid nephrosis" has never been observed by them. Christian² in summarizing the reported cases, was impressed by the short duration of the illness and wondered what influence the terminal infections might have had in the final pathologic picture. He was led to the conclusion that nephrosis should be regarded as one of the varieties of chronic nephritis and not as a distinct clinical entity. Using special stains in cases of clinical nephrosis, Bell³ was able to demonstrate that the chief pathologic difference that exists between glomerulonephritis and lipoid nephrosis is that in the latter "the glomerular capillaries are damaged but not completely obstructed."

The following case is reported because of the scarcity in the literature of cases which both fulfill the requirements for the clinical diagnosis of nephrosis and have been subjected to careful pathologic study. An unique feature of this patient's case was the termination in uremia which developed, under observation, without the usual elevation in blood pressure. The clinical data and sections were submitted to several pathologists specially interested in the renal problem, and their opinions and pathologic diagnoses are appended.

CASE HISTORY

E. P. F., a 25-year-old American-born housewife, entered the Peter Bent Brigham Hospital on January 27, 1933, complaining of swelling of the legs for three weeks.

The family history was irrelevant. The past history revealed that the patient had developed asthma at the age of seven years following a severe bronchitis. Intermittent attacks of severe asthma had continued thereafter. In 1927 she was admitted to the hospital because epinephrine and morphine failed to relieve an asthmatic attack. The physical examination showed emphysematous lungs and hypertrophied tonsils. Roentgenograms of the chest confirmed the clinical findings of emphysema and disclosed, in addition, a diffuse increased fibrosis at both bases. The blood Wassermann reaction was equivocally positive on two occasions. The urine examination was negative. In 1929 she was delivered normally of a male child in another hospital, but there was no record of a urine examination at that time. In 1931 the patient underwent a classical Caesarian section, at which time she was sterilized. The latter procedure was performed because chronic rheumatic heart disease with mitral stenosis had been discovered and the dependent edema that had persisted toward the end of the pregnancy was attributed to the lesion. In October

* Received for publication August 16, 1935.

From the Medical Clinic of the Peter Bent Brigham Hospital, Boston, Mass.
Department of Medicine, Northwestern University Medical School, Chicago, Ill.

1932, she was admitted again to the Peter Bent Brigham Hospital because of an uncontrollable attack of asthma. She was treated with epinephrine, morphine, autogenous vaccine and various barbituric acid derivatives. The blood Wassermann reactions, on three occasions, were one plus, doubtful and negative. The Hinton reaction was negative in all three instances. Lumbar puncture revealed no abnormalities of the spinal fluid.

The patient's health was fair following her discharge in October 1932, permitting her to perform her daily housework, although daily attacks of asthma necessitated epinephrine injections. Several times in the preceding five years she had noted slight edema of the ankles, and on January 5, 1933, she again noted edema of the lower extremities. On January 19, after an injection of epinephrine in her leg, she noted that fluid was escaping from the hypodermic wound in amounts sufficient to soak her stocking. The edema steadily grew more marked, and on one occasion she noted swelling of her eyelids. In addition to the edema, there was blurring of vision, spots before the eyes and marked dyspnea, but these symptoms were relieved temporarily by a watery diarrhea that followed the administration of magnesium sulphate. Thirst developed, accompanied by a decreased output of a dark colored urine. Occasional attacks of pain over the lumbar regions were relieved by hot water bags. There was a gradual but marked loss of strength. No antecedent history of upper respiratory infection could be obtained.

The physical examination on admission showed the patient to be well developed and nourished, extremely pale and markedly orthopedic. There was marked edema of the eyelids and conjunctivae. The ophthalmoscopic examination showed indistinct discs, and the surrounding fundi were pale. There were no evidences of vascular disease. The breath was bland, and there was no oral infection. The heart was slightly enlarged, and on auscultation systolic and diastolic murmurs were heard at the apex. The blood pressure was 110 systolic and 70 diastolic. Peripheral arteriosclerosis was absent. The examination of the chest showed the usual asthmatic squeaks, and there were a few coarse râles at the bases. Marked soft pitting edema was present in both legs, diminishing toward the upper thigh but present in the upper abdominal wall and back.

On admission the patient was considered to be primarily a cardiac problem because of the edema, dyspnea and findings of mitral stenosis. She was menstruating and the discovery of urinary albumin and red blood cells was ascribed to this. The underlying lesion in the kidneys was not suspected until a catheterized specimen disclosed a specific gravity of 1.045 and a very large trace of albumin, numerous casts of all descriptions and a rare red and white blood cell. A small amount of doubly refractile lipid material was detected. These urinary findings remained comparatively unchanged during the patient's two months in the hospital. The phenolsulphonephthalein dye excretion was 42 per cent after intravenous administration. The fluid intake was limited to 1000 c.c. daily, and the output was constantly around 200 c.c. in 24 hours. At the onset, the daily excretion of urinary protein was 6.1 gm. and this increased gradually to 20 gm. daily.

The total protein in the blood serum was low, and the albumin-globulin ratio was reversed (table 1). The blood cholesterol was high but decreased terminally. At first there was no appreciable retention of nitrogenous end-products but toward the end the non-protein nitrogen reached 174 mg. The first blood urea nitrogen determination was 20 mg. per 100 c.c. Three days later the non-protein nitrogen was 31 mg. per 100 c.c. The red blood count and hemoglobin determinations were normal in the beginning but diminished progressively. The blood pressure was never high and steadily decreased to questionable readings of 40 systolic and 20 diastolic. The basal metabolic rate, using the patient's ideal weight, was minus 19 per cent on two occasions. The Wassermann and Hinton reactions of the blood serum were doubtful, and no objective signs of syphilis could be found.

The patient was very cooperative, but failed to respond to the usual methods of therapy. Although she received adequate amounts of digitalis, the drug had no effect. Mersalyl (salyrgan) in 2 c c doses, given intravenously, increased the urinary output to 750 c c, 1620 c c and 1780 c c on three trials, but because of the difficulty encountered in the administration by this route, it was given intramuscularly. This proved to be very painful, and, because it resulted in a urinary output of only 970 c c, the use of this preparation was abandoned. Theophyllin (theocin) was likewise without diuretic effect. A high protein intake was attempted but not well tolerated and was without benefit. Southey tubes were used and abdominal paracenteses were performed. On one occasion 900 c c and 1075 c c of fluid were removed from the right and left pleural spaces respectively, relieving her dyspnea somewhat.

Her course in general was downhill. Four days before death she developed a pericardial friction rub. There was no fever. She became more anemic, the blood pressure decreased steadily, nitrogen retention increased, urinary protein excretion increased, the plasma carbon dioxide combining power fell to 32 volumes per cent and there was generalized twitching of the body muscles. She became comatose and died March 29, 1933, 62 days after her admission to the hospital.

The pathologic examination showed the skin to be of a waxy, livid color and pasty consistency. Anasarca was present, it was more marked in the lower extremities. The pericardial cavity contained 75 c c of a cloudy fluid with some fibrin. The pericardial surfaces were covered by numerous fibrinous adhesions.

The heart weighed 340 gm. The lesions present were limited to the mitral valve, the leaflets of which were thickened and shortened. The endocardium at the mitral valve showed a small organizing vegetation, which was interpreted as rheumatic, but which might have been an acute bacterial vegetation. A few gram-positive cocci were demonstrated in the blood clot near the vegetation but not in the fibrinous portion of it. The aorta was uniformly elastic and showed only slight fatty infiltration of the intima. There were no atheromatous plaques. The peripheral vessels were negative, and no signs of arteriosclerosis or syphilis could be found.

Microscopically, the lungs showed marked passive congestion and a patchy bronchopneumonic infiltration. Streptococci were found in the sections. The characteristic changes of asthma were minimal.

The spleen weighed 300 gm and showed evidences of edema. The microscopic changes were those of an acute splenitis. The pancreas showed acute diffuse pancreatitis with moderate acinar atrophy and fat necrosis.

The liver weighed 1950 gm and was softer than normal. It presented a brownish yellow mottled color which suggested marked fatty metamorphosis. There was moderate congestion. The liver cells, microscopically, showed marked fatty metamorphosis. These fatty deposits were mainly periportal and central in location. The portal systems were everywhere almost completely surrounded by fatty liver cells, although the elements of the portal systems were not remarkable. The liver cells in the central areas were the only ones reasonably well preserved.

The right kidney weighed 395 gm, the left 390 gm. They were of normal shape with the fetal lobulations indistinctly preserved. They were markedly swollen, very pale and of softer than normal consistency. The perirenal fat was edematous and easily removed. The capsule was thin, smooth and glistening and was not appreciably adherent. After stripping the capsule, the kidney surface was smooth. The edges tended to evert. The cortex uniformly measured 12 to 13 mm in thickness. The glomeruli did not stand out. The medullary rays were not distorted. The definition of the tubular striations was fairly well preserved, but they, too, were rather pale.

The microscopic examination of the kidneys showed edema of the capsule but no increase in fibrous tissue. There were occasional foci of lymphoid cells beneath the capsule and throughout the renal parenchyma, but there was no accom-

panying necrosis of tissue. Migrating polymorphonuclear leukocytes were scattered throughout the interstitial tissues. There was a marked generalized edema and a distinct interstitial fibrosis. The afferent vessels showed no sclerosis, and none were completely or partially occluded. The glomerular tufts were quite bloodless and shrunken, and the capillaries showed no endothelial proliferation. There was a slight hyalin thickening of the basement membranes. There were no atrophic or hyalinized glomeruli, but rarely a glomerulus showed some capsular proliferation and capsular adhesion. The glomeruli appeared surprisingly normal, and on the whole, the renal tissue was fairly well preserved. Characteristic changes of an acute or chronic glomerulonephritis were absent. The tubules were dilated. They contained an unusual amount of albuminous precipitate and numerous hyalin and cellular casts. The tubular epithelium had an unusually high fat content. Fat was largely present in the cells and lumina of the convoluted tubules. Vacuolization and colloid degeneration were prominent throughout. Flattened, cuboidal, regenerated tubular lining cells were common. Necrosis and desquamation of epithelium were noted in many fields.

FIG 1 Section of the kidney (H and E stain, magnified 95 times) showing the bloodless and shrunken glomerular tufts, interstitial edema and fibrosis, dilated tubules containing albuminous precipitate and hyalin and cellular casts

The arteries showed no sclerosis and none were occluded. There was no passive congestion. The interlobar veins were almost completely occluded bilaterally by thrombi. The thrombi contained slightly hyalinized strands of fibrin and entrapped leukocytes. In one kidney a thrombus showed early organization. The thrombi were interpreted as being of recent origin because they were, for the most part, unorganized. The renal parenchyma showed no hemorrhagic necrosis.

Special stains of the kidney, such as phosphotungstic acid hematoxylin, Lee Brown, aniline blue and Scharlach R, contributed little to the histologic study. None demonstrated any significant glomerular changes. Dr S B Wolbach was impressed by the interstitial edema, interstitial fibrosis, the diminution in the number of capillaries between the tubules and the slight focal interstitial round cell infiltration. These changes with the tubular vacuolization and fatty metamorphosis constituted the outstanding changes in the kidneys.

Blood cultures and cultures from the kidney were negative.

Anatomic Diagnoses Tubular nephritis (lipoid nephrosis), thrombosis of interlobar veins. Vegetative endocarditis of the mitral valve, mitral stenosis and insuf-

iciency Pericarditis, fibrinous, bronchopneumonia (right, acute) Passive congestion of viscera, anasarca, ascites (750 cc), hydrothorax, bilateral, hydropericardium (75 cc) Pancreatitis with fat necrosis (acute) Fatty metamorphosis, liver, marked Occlusion Fallopian tubes (post-operative)

COMMENT

No history of an inciting infection could be obtained in this case. Because of the numerous entrances into the hospital, repeated Wassermann reactions were on record, and every effort was made to establish syphilis as the etiologic agent. At no time, however, could the Wassermann reaction be considered to be positive, and no stigmata of this disease could be found. No reason for the many weakly positive reactions could be ascertained. The absence of a chronic wasting disease made amyloidosis seem unlikely. The postmortem examination confirmed the absence of these factors. In addition, there was no association with the previous pregnancies that could be traced.

The onset of the disease definitely occurred within the three months' period following the previous hospital admission, but was so gradual that the patient's complaints dated from the time that the massive edema was present. The whole picture was complicated by the long standing chronic rheumatic heart disease and asthma. These, however, did not contribute to the patient's death.

Clinically, shortly after admission, this patient was considered to be a well marked case of the nephrosis syndrome. The scant initial elevation of the blood urea nitrogen had been noted, and three days after admission the non-protein nitrogen was normal. The lack of response of this patient to the usual therapeutic procedures was no surprise. However, with the development of the azotemia that steadily grew more pronounced, the glomeruli were visualized as undergoing marked pathologic change, another example, then, of nephrosis developing terminally into glomerulonephritis.

Pathologically, however, the kidneys were, in every respect, typical of the so-called "pure," "genuine" or "lipoid" nephrosis. The tubules showed the characteristic degenerative lesions. The glomeruli, while not normal, could not be considered to be characteristic of those usually seen in glomerulonephritis. Evidences of a blood stream infection were noted, which had been unsuspected clinically. There had been no fever. The exact nature of this bacterial invasion could not be determined with certainty, but the belief that it was streptococcal was based upon the finding of these organisms in the clots along the mitral valve, the typical streptococcal patchy bronchial pneumonia and the demonstration of these organisms in the microscopic sections of the lungs and the inflammatory lesions of the pancreas and spleen. The negative blood cultures cannot rule out the presence of this terminal septicemia.

The unusual thromboses observed in the renal veins were recent in origin and the part played by these lesions in the uremia cannot be answered with any degree of surety. However, these lesions probably played a part in hastening the end rather than initiating the onset of the uremia.

Because of our inability to state with certainty the factors leading to the fatal uremia and their relative importance, we submitted the slides together with the clinical history to several well-known pathologists interested in the renal problem. The following courteous and interesting replies were made independently, are illuminating and require no further comment.

(1) One stated, "From the history and the slides, this seems to me to be unequivocally a case of chronic nephrosis ('lipoid nephrosis')"

(2) Another considered the clinical and pathological aspects as representing nephrosis or degenerative Bright's disease. The microscopic study, according to him, shows the kidney to be characterized by edema, tubular epithelial atrophy and degeneration and a heavy precipitate of protein and casts within the tubules. The extreme degree of edema and precipitated protein and casts gives the striking microscopic appearance. The venous thrombi were considered to be a possible explanation for the unusual histologic appearance even with the lack of passive congestion present, and the increase in venous pressure may have borne some relation to the edema of the kidney tissue.

(3) Still another considered the case as one of severe toxic nephrosis, not "lipoid", and suggested morphine as the toxic agent since it can produce a similar picture in susceptible individuals. (Although we administered morphine frequently and freely, we could not gather evidence pointing to a chronic morphine addiction nor to the possibility of a supply other than what she received at our hands for the treatment of the asthma. According to the records, morphine was first administered in 1927. During her last hospital admission, morphine or codeine was given from one to three times daily.)

(4) Another wrote, "The kidney shows glomeruli which are typical of chronic lipoid nephrosis. The glomeruli show narrow capillaries, the narrowing being due, for the most part, to thickening of the capillary basement membrane. The tubules contain a large amount of precipitated albumin and a great many casts. The dilatation of the tubules may be due to obstruction by the casts. In this particular case the marked renal insufficiency that developed is probably caused by obstruction of the tubules by casts. This feature is not seen usually in lipoid nephrosis, but I have seen one case with a similar obstruction resulting in uremia. If the casts were not present a kidney in this condition would show only a moderate nitrogen retention. The clinical picture corresponds to what one would expect from the anatomic changes except that, as a rule, the blood pressure is elevated with this type of renal lesion."

"In studying a large group of cases of glomerulonephritis a great variety of structural changes is found and it is not possible to separate sharply the types due to endothelial proliferation from those due to thickening of the basement membrane. In many cases both the basement membrane and the endothelium take part in the capillary obstruction. There is, however, a fairly large group of cases which resemble this one in that the chief obstruction is due to thickening of the basement membrane. Personally, I do not believe that lipoid nephrosis is sharply separable from other forms of glomerulonephritis, but those in which the basement membrane of the glomerular capillaries is prominently involved usually give a story as is present in your case."

(5) Another wrote, "The marked albuminuria indicates that the glomeruli were hyperpermeable in spite of the absence of demonstrable changes in the majority of them. The arterioles were likewise free from change. The retention of nitrogenous waste products must have been due, therefore, to some cause outside the glomeruli and blood vessels. One or more of the following factors may have been responsible — (1) The diversion of water into the tissues caused the marked oliguria. The output of urine may have been insufficient even when greatly concentrated, to excrete a sufficient amount of urea. The

importance of this factor in this case can be determined in some measure by the effect of mersalyl on blood urea (2) Edema of the interstitial tissue of the kidney was of sufficiently high degree to cause considerable increase in intrarenal pressure with interference with the renal circulation The fact that the glomeruli were practically bloodless, in spite of the obstruction (thrombosis) in the renal veins, suggests that this was an important factor in the retention (3) Plugging of the tubules with casts was of sufficient extent to be included among the possible factors in causing retention In my opinion, increased intrarenal pressure due to edema of the kidneys themselves and oliguria due to diversion of water into the tissues are the most important of the factors mentioned

"In my opinion, this is a case of glomerulonephritis for the following reasons (1) A limited number of glomeruli did contain epithelial crescents or adhesions between the glomerular tufts and the capsule of Bowman (2) Occasional foci of lymphocytic infiltration were present in the sections (3) The presence of casts in such enormous numbers would seem to exclude this case rather definitely from the category of nephrosis (4) Although the cholesterol of the blood was increased, the degeneration of the tubular epithelium was said to be fatty instead of lipoidal"

SUMMARY

A woman, 25 years of age, developed the clinical picture of nephrosis typical in all respects except a slight questionable nitrogen retention which became marked terminally without, however, the expected rise in blood pressure Death occurred after 62 days of careful observation in the fifth month of the disease Postmortem evidence was found of a terminal, probably streptococcal, general infection

The kidneys showed tubular changes characteristic of nephrosis with glomerular damage minimal or almost entirely absent The various interpretations of competent pathologists especially interested in the renal problem illustrate the confusion surrounding the subject of nephrosis In the case reported the microscopic picture commonly considered typical of nephrosis was associated with clinical findings (azotemia) usually produced by a form of glomerulonephritis

It would seem that the word nephrosis should be restricted to a convenient term for a clinical syndrome rather than be used as a descriptive of a pathologic entity

I am deeply grateful to Drs H A Christian and J P O'Hare, on whose service this case was seen, for permitting its publication, to Drs S B Wolbach, J P Simonds, W H Nadler, and M H Barker for their many valuable criticisms and suggestions and to Miss Margaret Driscoll who performed the chemical determinations My thanks are also due the pathologists who were kind enough to review the case and submit to me their opinions

EDITORIAL

THE AMERICAN BOARD OF INTERNAL MEDICINE

The American Board of Internal Medicine incorporated February 28, 1936, completed its organization on June 15, 1936. The officers chosen were Walter L. Bierring, M D, Des Moines, chairman, Jonathan C. Meakins, M D, Montreal, vice-chairman, and O. H. Perry Pepper, M D, Philadelphia, secretary-treasurer. These officers with the following six members constitute the present membership of the Board: David P. Barr, M D, St. Louis, Reginald Fitz, M D, Boston, Ernest E. Irons, M D, Chicago, William S. Middleton, M D, Madison, John H. Musser, M D, New Orleans, and G. Gill Richards, M D, Salt Lake City.

The term of office of each member shall be three years and no member shall serve more than two consecutive three-year terms.

The organization of the Board is the result of effective effort on the part of the American College of Physicians in conjunction with the Section on Practice of Medicine of the American Medical Association, and these two organizations are represented in the membership of the Board on a five to four ratio respectively.

The American Board of Internal Medicine had previously received the official approval of the two bodies fostering its organization, as well as that of the Advisory Board for Medical Specialties and the Council on Medical Education and Hospitals of the American Medical Association.

The purpose of the Board shall be the certification of specialists in the field of internal medicine, and the establishment of qualifications with the required examination procedure for such certification.

The value of such certification can be stated as (1) an attest of special training and qualification for the practice of internal medicine as a specialty, (2) registration with proper designation in the directory of the American Medical Association, and (3) the certificate will constitute an essential requirement for election to Fellowship in the American College of Physicians.

While the Board is at present chiefly concerned with the qualification and procedure for certification in the general field of internal medicine, it is intended to inaugurate immediately after July 1, 1937, similar qualification and procedure for additional certification in certain of the more restricted and specialized branches of internal medicine, as gastroenterology, cardiology, metabolic diseases, tuberculosis, allergic diseases, et cetera. Such special certification will be considered only for candidates who have passed at least the written examination required for certification in general internal medicine. The operation of such a plan will require the active participation and cooperation of recognized representatives from each of such special fields of medicine.

Each applicant for admission to the examination in internal medicine will be required to meet the following standards

General Qualifications

- 1 Satisfactory moral and ethical standing in the profession
- 2 Membership in the American Medical Association or, by courtesy, membership in such Canadian or other medical societies as are recognized for this purpose by the Council on Medical Education and Hospitals of the American Medical Association Except as here provided, membership in other societies will not be required

Professional Standing

- 1 Graduation from a medical school of the United States or Canada recognized by the Council on Medical Education and Hospitals of the American Medical Association
- 2 Completion of an internship of not less than one year in a hospital approved by the same Council
- 3 In the case of an applicant whose training has been received outside of the United States and Canada, his credentials must be satisfactory to the above Council, the Advisory Board for the Medical Specialties and the National Board of Medical Examiners

Special Training

- 1 Five years must elapse after completion of a year's internship in a hospital approved for intern training, before the candidate is eligible for examination
- 2 Three years of this period must be devoted to special training in Internal Medicine This requirement should include a period of at least several months of graduate work under proper supervision in Anatomy, Physiology, Biochemistry, Pathology, Bacteriology, or Pharmacology, particularly as related to the practice of Internal Medicine, or it may include a period of at least several months of graduate work under proper supervision in Internal Medicine or in its restricted and specialized branches This graduate work may be carried on in any domestic or foreign medical school, laboratory, hospital, clinic or dispensary, recognized by the Council on Medical Education and Hospitals of the American Medical Association as offering appropriate facilities for this type of postgraduate experience
- 3 A period of not less than two years of special practice in the field of Internal Medicine, or in its more restricted and specialized branches

The American Board of Internal Medicine does not propose to establish fixed rules for the preliminary training of candidates for certification in this field Broad general principles for training, however, may be outlined, although such suggestions as are

made must of necessity be subject to constant changes reflecting the dynamic nature of the specialty

A sound knowledge of Physiology, Biochemistry, Pharmacology, Anatomy, Bacteriology, and Pathology in so far as they apply to disease is regarded as essential for continued progress of the individual who practices Internal Medicine. The mere factual knowledge of Medicine and its basic sciences is not sufficient. The candidate must have had training in their use in furthering his understanding of Clinical Medicine. This implies practical experience under the guidance of older men who bring to their clinical problems ripe knowledge and critical judgment. Preparation to meet this requirement adequately may be even more difficult to obtain than the so-called scientific training. It may, however, be acquired in the following ways

- (a) By work in a well-organized Hospital Out-Door Clinic conducted by competent physicians,
- (b) By a prolonged period of resident hospital appointments likewise directed by skilled physicians,
- (c) By a period of training in intimate association with a well-trained and critical physician who takes the trouble to teach and guide his assistant rather than to require him only to carry out the minor drudgery of a busy practice

- 4 The Board does not consider it to the best interests of Internal Medicine in this country that rigid rules as to where or how the training outlined above is to be obtained. Medical teaching and knowledge are international. The opportunities of all prospective candidates are not the same. Some may have the opportunity of widening their knowledge by a period of study abroad. Others, at the other extreme, may be restricted to a comparatively narrow geographic area and their more detailed training must be obtained in short periods scattered over a longer time. Although it is laid down that at least five years must elapse between the termination of the first intern year, and when the candidate is eligible to take the examination, a longer time is advisable. The Board wishes to emphasize that the time and training are but a means to the end of acquiring a broadness and depth of knowledge of Internal Medicine which the candidate must demonstrate to the Board in order to justify it in certifying that he is competent to practice Internal Medicine as a specialty. The responsibility of acquiring the knowledge as best he may rests with the candidate, while the responsibility of maintaining the standard of knowledge required for certification devolves on the Board.

Method of Examination

The examination required of candidates for certification as specialists in Internal Medicine will comprise Part I (written), and Part II (practical) or (clinical)

Part I The written examination is to be held simultaneously in different centers of the United States and Canada and will include

(a) Questions in applied Physiology, Physiological Chemistry, Pathology, Pharmacology, and the cultural aspects of medicine

(b) Questions in general Internal Medicine

The first written examination will be held in December, 1936, and candidates successful in this written test will be eligible for the first practical or clinical examination which will be conducted by members of the Board near the time of the annual session of the American College of Physicians at St. Louis in April, 1937. Another written examination will be held in February, 1937, followed by a practical test in Philadelphia in June, 1937.

The fee for examination is forty dollars which must accompany the application, and an additional fee of ten dollars is required when the certificate is issued.

Application blanks and further information can be obtained by addressing the office of the chairman, Room 1210, 406 Sixth Avenue, Des Moines, Iowa, U. S. A. The organization of the American Board of Internal Medicine is largely due to the initiative of the American College of Physicians, and as such, will be regarded one of its most worthwhile accomplishments.

The certification procedure will distinctly influence the Standards of Fellowship in the College and likewise be a motive force towards higher ideals of internal medicine in America.

REVIEWS

Fundamentals of Biochemistry in Relation to Human Physiology By T R PARSONS
Fifth Edition 453 pages, 13 × 19 cm Wm Wood and Co, Baltimore 1935
Price, \$3 00

This is the fifth edition of this work, which first appeared in 1923, and which has retained an undiminished and deserved popularity ever since. The author's style is clear and lucid and he has succeeded in meeting the needs of those with a minimum of previous knowledge of pure chemistry and physics. In this edition he has kept step with important chemical advances of practical interest. At the end of each chapter is a well selected bibliography for further reading. No doubt this is one of the best books now available which embraces within a reasonable compass and in a clear and simple manner most of the important information which the well informed practitioner requires in this field.

G A H

Immunology By NOBLE PIERCE SHERWOOD, Ph D, M D, Professor of Bacteriology, University of Kansas, and Pathologist to The Lawrence Memorial Hospital, Lawrence, Kansas 608 pages, 16 × 23.5 cm C V Mosby Company, St Louis 1935 Price, \$6 00

The preparation of this book has resulted from the author's experience in the teaching of immunology to medical students and the college students whose major work has been in bacteriology. It has been written primarily for them rather than for those intending to specialize in immunology. Sherwood has attempted to present this science in such a manner as to induce the student to correlate with it some of his knowledge of other subjects and to utilize this knowledge in the explanation both of infection and resistance and of the various serologic procedures. The practical application of these procedures is also discussed. In general the subject is well presented but at times the discussion is rather brief. There is, however, a good list of references at the end of each chapter for the use of the student who wishes more detailed information about some particular phase of immunology. This book should be of value to those for whom it has been written.

F W H

The Balanced Diet By LOGAN CLENDENING, M D 207 pages, 13 × 19 cm D Appleton-Century Co, New York 1936 Price, \$1 50

This is another of the group of low-priced books on diet and allied subjects for popular consumption which have appeared in increasing numbers this year. The author is well known for his syndicated press articles on medical topics, and the book is written in a popular, informal style. There is some fresh historical material upon dietetics which is of interest. The publishers have included some extraordinarily crude sketches illustrating the plight of unfortunates with various vitamin deficiencies.

The advisability of including the chapter on Diet in Disease in a book of this type is at least debatable. There is an interesting discussion of food fads. At the back the book is provided with the customary food tables and other similar data.

G A H

A Handbook of Urology By VERNON PENNELL 224 pages, 13 × 19 cm The Macmillan Company, New York 1936 Price, \$2.75

This small handbook represents an attempt to place in the hands of students and practitioners a simple outline of the facts which must be accumulated and evaluated in the process of reaching a diagnosis in the field of urology. It contains much of value. The chapter on genito-urinary tuberculosis is of especial interest. On the other hand it seems open to criticism that a discussion of the venereal diseases is not included. Moreover, in view of the object of the book there is a disproportionate amount of space devoted to description of operative procedure and not enough consideration of pathology and of diagnosis.

W H T

New Pathways for Children with Cerebral Palsy By GLADYS GACE ROGERS and LEAH C THOMAS 167 pages, 14 × 20.5 cm The Macmillan Company, New York 1935 Price, \$2.50

The practical management of cerebral spastic palsy has always been difficult due to the medical condition of the patient, the psychological reaction of the parents and the few therapists available with a suitable attitude toward and aptitude for the very slow and complicated procedures. The authors have presented most completely and thoroughly the principles of treatment which have been known but which have never been well coordinated. The book is very interestingly written so that even the technical angles will be understood by the average layman.

All the various types of apparatus employed are so simple that they can be duplicated in the home, and their use is easily understood. The extensive and variable list of games and methods of developing mental and physical coordination will be of tremendous aid to technicians, parents and clinicians.

Of particular interest is the chapter entitled "Responsibilities of the Parents" which briefly but forcibly states the essentials of proper care of the spastic child in the home. "Robin Hood's Barn" must be a most fascinating and interesting place.

The appendix offers a simple but accurate record system for recording improvement changes. The bibliography is broad and complete. The reviewer believes that this book is an important addition to the literature of cerebral palsy. It covers a field generally neglected by the medical profession. It is recommended to physicians and parents.

A V

Allergy of the Nose and Paranasal Sinuses A Monograph on the Subject of Allergy as Related to Otolaryngology By FRENCH K HANSEL, M D, M S 820 pages, 18.5 × 26 cm, with 58 illustrations and 3 color plates C V Mosby Co, St Louis, Mo 1936 Price, \$10.00

The title of this work suggests that its scope is rather narrow, limited to a discussion of allergic manifestations in the nose and sinuses. The secondary title expresses more adequately its completeness. Fifteen of the 35 chapters are devoted to the nose and sinuses, 20 to the subject of allergy in general, without specific reference to the upper respiratory tract.

The author has assembled and organized a great mass of information on the physiology, biochemistry, cellular reactions, and bacteriology of the nose and paranasal sinuses, in the normal, allergic and infected states. The discussion of the effect of drugs on nasal physiology is interesting and important, as it emphasizes the harmfulness of certain local applications commonly used in the nose. The chapter on histology and histopathology is fully illustrated.

Chapters VIII to XV review the subject of allergy in general. The origin and development of our concept of allergy, history taking and methods of testing, are fully and clearly presented, without the confusion frequently seen in writings on this subject.

Chapters XVI to XX discuss the nasal manifestation of allergy, the cytology of the nasal secretions, differential diagnosis and sinus complications in allergy, with one chapter on the roentgen-ray examination of the sinuses. Other chapters on urticaria, headache, bronchial asthma, bronchoscopy, allergic lesions of the ear, and allergy and immunology in ophthalmology round out the work. Chapter XXX, on treatment, is very complete.

The final chapters are devoted to the subject of hay fever, botany and geography of offending plants, chemistry, immunology, symptomatology, diagnosis, and treatment of hay fever.

The reviewer feels that this book is a valuable contribution. The literature is covered fully, digested well and presented clearly. It is certainly a most complete work on an important subject.

COLLEGE NEWS NOTES

GIFTS TO THE COLLEGE LIBRARY

Acknowledgment is made of the receipt of the following gifts to the College Library of publications from members

Dr Frederick T Lord (Fellow), Boston, Mass—1 autographed book, "Lobar Pneumonia and Serum Therapy",

Dr Herman O Mosenthal (Fellow), New York, N Y—1 autographed book, "The Diagnosis and Treatment of Variations in Blood Pressure and Nephritis",

Dr Julius P Dworetzky (Fellow), Liberty, N Y—1 reprint,

Dr Norbert Enzer (Fellow), Milwaukee, Wis—14 reprints,

Dr Marjorie E Reed (Fellow), Plymouth, Pa—3 reprints,

Dr Ramon M Suarez (Fellow), San Juan, P R—1 reprint

Dr Jacob Gutman (Fellow), Brooklyn, N Y—"Seventh Supplement to 'New Modern Drugs'",

Dr Philip B Matz (Fellow), Washington, D C—1 reprint,

Dr Jacob Greenstein (Associate), Providence, R I—1 reprint,

Dr John S Hibben (Associate), Pasadena, Calif—1 reprint,

Dr Bert F Keltz (Associate), Oklahoma City, Okla—1 reprint

WASHINGTON ACADEMY OF MEDICINE

The Washington Academy of Medicine, Washington, D C, has been organized with a membership limited to 60, of whom one-half must be non-medical men but workers in medical science. It is one of the objects of the Academy to bring such men and such physicians more closely together. Dr William A White (Fellow) is President. In addition to Dr White, among the Charter members, appear the following Fellows of the College

Dr Walter A Bloedorn

Dr Walter Freeman

Dr Edgar E Hume

Dr George W McCoy

Dr Earl B McKinley

Dr William J Mallory

Dr Matthew W Perry

Dr Charles R Reynolds

Dr Perceval S Rossiter

Dr Joseph F Siler

Dr Walter L Treadway

Among its medical members also are 11 Fellows of the American College of Surgeons

ALPHA GAMMA MU ALPHA

A new organization Alpha Gamma Mu Alpha, a postgraduate medical fraternity, was formed at Kansas City during the last meeting of the American Medical Association. The stated object of this Society is "to promote thought". There are no dues, and the initiation fee is one dollar. Meetings will be held when and where the American Medical Association meets. Members must belong to their County and State Medical Societies and the American Medical Association. Dr Arthur E Guedel, Beverly Hills, Calif, is President, Dr LeRoy S Peters (Fellow), Albuquerque, N M, is Secretary-Treasurer, and Dr John W Shuman (Fellow), Los Angeles, Calif, is Delegate.

Dr Charles J Bloom (Fellow), New Orleans La, as a faculty member of the Southern Pediatric Seminar, lectured and conducted clinics on July 27 through August 2, inclusive, at Saluda, N C

Dr Bloom participated in the Postgraduate Course, July 6 to 18, incl, of the Flint-Goodridge Hospital of Dillard University

He also conducted a pre-school clinic in Bay St Louis, Miss, June 19, sponsored by the Parent-Teachers' Association U S Public Health Service and the physicians of Harrison County, Miss

Dr George M Decherd, Jr (Associate), formerly Instructor in Medicine at the University of Texas School of Medicine, Galveston, has accepted an appointment as Assistant Professor in the Department of Medicine of Louisiana State University, New Orleans, his appointment taking effect as of July 1, 1936

The fifty-sixth annual meeting of the Lehigh Valley Medical Association was held at Pocono Manor, Pa, July 15, under the presidency of Dr J K Williams Wood (Associate), Willow Grove, Pa

Dr John H Musser (Fellow), New Orleans, Professor of Medicine at Tulane University of Louisiana School of Medicine, was the guest speaker, his subject being "Abdominal Pain Due to Extra-Abdominal Disorders"

Major General Charles R Reynolds (Fellow), Surgeon General of the U S Army, received the honorary degree of Doctor of Science from Dickinson College, Carlisle, Pa, in June

Dr William G Herrman (Fellow), Asbury Park, N J, has been elected a Vice-President of the Medical Society of the State of New Jersey

Dr Joseph Frederick Panton (Fellow), Buffalo, has received the appointment of Associate in Medicine at the University of Buffalo School of Medicine

Dr Isidore W Held (Fellow), New York City, has been appointed Clinical Professor of Medicine at the New York University College of Medicine

Dr Chester W Waggoner (Fellow), Toledo, Ohio, has been appointed a member of the Ohio State Medical Board for a term of seven years

Dr Edward H Schwab (Fellow), Galveston, has been elected President of the Texas State Heart Association, Dr Robert M Barton (Fellow), Dallas, was elected Secretary

Dr Frank C Hodges (Fellow), Huntington, W Va, has been elected a Vice-President of the West Virginia Medical Association Dr Hodges delivered the annual oration in medicine, "The Diagnostic Value of Intradermal Injections," at the State meeting held in Fairmont, June 8 to 10

Dr Walter M Simpson (Fellow), Dayton, Ohio, is Chairman of the American Committee for the First International Congress on Fever Therapy, which was to have been held in September, but has now been postponed until March 30 to April 2, 1937 The sessions will be held at the College of Physicians and Surgeons of Columbia University, New York City

Dr Francis M Pottenger (Fellow), Monrovia, Calif, has been elected President of the American Association for the Study of Internal Secretions

Dr Hugh S Cumming (Fellow), formerly Surgeon General of the U S Public Health Service, has been elected President of the Pan-American Conference of National Directors of Health

Dr William S Middleton (Fellow), Dean of the University of Wisconsin Medical School, Madison, delivered the first Harry A Sifton Memorial Lecture at the Milwaukee Hospital, May 21, on "The Tools with Which We Work"

Dr T M Durant (Associate), formerly of Tucson, Ariz, has been appointed Assistant Professor of Internal Medicine at Temple University School of Medicine, Philadelphia, Pa, effective August 1

Dr Lewis H Hitzrot (Associate), formerly of Philadelphia, has accepted the Medical Directorship of the Meicersburg Academy, Meicersburg, Pa, effective September 1

Dr Langley Porter (Fellow), San Francisco, has retired as Dean of the University of California Medical School, but will continue his affiliation with an emeritus status as an adviser in administration and research Dr W McKim Marriott (Fellow), St Louis, succeeds Dr Porter as Dean

Dr Henry A Christian (Fellow), Hersey Professor of Theory and Practice of Physic, Harvard University Medical School, will deliver the third Frank Billings Lecture of the Thomas Lewis Gilmer Foundation before a joint meeting of the Institute of Medicine of Chicago and the Chicago Society of Internal Medicine, October 26, on "Edema, Diuretics, Diuresis"

Dr Leo Loeb, Edward Mallinckrodt Professor of Pathology, Washington University School of Medicine, St Louis, and the 1935 John Phillips Memorial Medalist of the American College of Physicians, has announced his retirement at the end of this year

Dr Matthew Shapiro (Associate), New York City, represents Internal Medicine in a group of physicians appointed by the Board of Directors of the Associated Hospital Service of New York to serve in an advisory capacity, especially regarding the eligibility of subscribers to services under the hospital plan

Dr Cecil Striker (Fellow), Cincinnati, Ohio, has been appointed Chairman of a special committee on diabetes formed by the Public Health Federation of Cincinnati, in cooperation with the Academy of Medicine of Cincinnati The Committee will establish a bureau of information for physicians and the public, to carry on a study of the morbidity and mortality of diabetes and to promote public health education concerning the treatment of diabetes

Dr Francis G Blake (Fellow), Sterling Professor of Medicine, Yale University, New Haven, was awarded the honorary degree of Doctor of Science by Dartmouth College at the past June commencement

Dr John Walker Moore (Fellow), Dean of the University of Louisville School of Medicine, has been given the University 1936 Award of Merit. From his citation, the following is quoted: "significant contribution through research on cardiovascular functions, establishment a decade ago of the student unit system of clinical instruction, effective and stimulating teaching." Dr Moore has been on the faculty of the University since 1915, having been Professor of Medicine since 1923 and Dean since 1928. He is a graduate of the University of Pennsylvania School of Medicine, 1912.

Dr William B Castle (Fellow and John Phillips Memorial Award Medalist, 1933, of the American College of Physicians) has recently been awarded the honorary degree of Doctor of Medicine by Utrecht University.

Dr Martha Tracy (Fellow), Dean of the Woman's Medical College of Pennsylvania, has resumed active duty after a year's leave of absence.

Dr Charles W Burr (Fellow), Philadelphia, has been appointed, by Mayor Wilson, a member of the advisory staff to supervise treatment of patients at the Philadelphia Hospital for Mental Diseases at Byberry.

Dr Martin E Rehfuess (Fellow), Dr Henry K Mohler (Fellow), and Dr Baldwin L Keyes (Associate), all of Philadelphia, have been advanced by Jefferson

Medical College to Professor of Clinical Medicine, Clinical Professor of Therapeutics and Clinical Professor of Psychiatry, respectively

Sir Frederick Banting (Fellow), Professor of Medical Research at the University of Toronto, has been elected to Fellowship in the Royal College of Physicians, London

Dr William Devitt (Fellow), Allenwood, Pa., has been reelected President of the Federation of American Sanatoria

OBITUARIES

DR JOHN DENNISTON WILSON

Dr John Denniston Wilson (Fellow), Scranton, Pa, died June 20, 1936, of coronary artery disease. He was born in Indiana, Pa, on October 13, 1879, attended the Indiana State Normal School and later graduated from the Jefferson Medical College of Philadelphia in 1905. From 1906 to 1908 he was Demonstrator in Pathology at Jefferson Medical College, from 1905 to 1908, Assistant Pathologist at the Philadelphia General Hospital, in 1910 he went to Scranton and became affiliated with the Scranton State Hospital and continued the association for twenty-five years. He was a Consultant at the Carbondale General Hospital and the Nanticoke State Hospital. He had pursued postgraduate study at Koemigsberg, Berlin, Vienna and at the University of Pennsylvania Graduate School of Medicine. He was a member of the Lackawanna County Medical Society, Pennsylvania State Medical Society, the American Heart Association, the American Medical Association, and had been a Fellow of the American College of Physicians since 1928. He was a volunteer during the Spanish-American War, and served on the Medical Advisory Board during the World War.

Dr Wilson had attained a position of prominence in the medical profession of his City and community. He took an active part in the affairs of his local society and was instrumental in bringing leading medical men to Scranton.

DR ARTHUR BROWN CHASE

Dr Arthur Brown Chase was born in Lynn, Massachusetts, on February 19, 1870. After attending school there he entered Harvard University School of Medicine, where he graduated in 1892. He interned for two years at the Lynn Hospital, and then remained for twelve years in his native city in private practice. He then went first to Atchison, Kansas, and later to Oklahoma City, where he remained the rest of his life. He married Florence Aldous (who survives him) on July 9, 1910.

He was a member of the Men's Dinner Club, a thirty-second degree Mason, a member of the Episcopal church, Alpha Kappa Kappa Medical Fraternity. He was made a Fellow in the College of Physicians in 1920, and was also a member of the Southern Medical Association.

He has been connected with the University of Oklahoma School of Medicine, after coming to Oklahoma City, in varying capacities up until 1926, when he was made a Professor of Clinical Medicine. In 1936 he was made Professor of Medical Ethics.

He took an active part in organized medicine, regularly attending meetings at home and abroad. He was a past president of the Oklahoma County Society and was Councilor of the State Association at the time of his death.

He gave freely of his time and talents in furthering the cause of organized medicine

A chronic heart lesion curtailed his activities, so he perfected himself in Cardiology. He was known well and most favorably in the State, as well as out of it in that particular branch of medicine

For the past two years he had been noticeably failing in health, but kept on with his work until July 8, on leaving his office, he fell and hit his head on a concrete pavement, producing a sub-arachnoid hemorrhage. He improved for a week and a faint hope was held for his recovery, when he began to sink and died July 20

Dr Chase was a genial soul and loved by his confreres. He especially liked to talk to medical students, interns, and those interested in medicine, and wielded a powerful influence for good with those with whom he came in contact. His numerous friends feel a great void since his passing

LEA A. RIELY, M.D., F.A.C.P.,
Governor for Oklahoma

DR. MARTIN J. SYNNOTT

Dr Synnott, the son of the late Mr. and Mrs. Joseph A. Synnott, was born in Great Neck, Long Island, in 1869. His parents moved to Montclair when he was one year old and he resided in that vicinity thereafter. He obtained his preliminary education in the public school of Montclair and graduated from the Montclair High School in 1887. Following this he entered Yale University from which he graduated with a B.A. degree in 1892. Two years later he obtained his M.D. degree from the College of Physicians and Surgeons of New York City.

In 1905 he received an M.A. degree from Yale which was followed by further graduate work abroad in the various clinics of Edinburgh, Berlin and Vienna. He also studied at St. Mary's Hospital, Paddington, London, and at the Harvard Medical School.

Dr Synnott was a prolific writer of medical articles and kept in close touch with everything medical or pertaining to public health in Essex County and was a member of the Montclair Board of Health.

He entered the World War as Captain and was discharged as Major in 1918. At the time of his death he was Colonel in the U.S. Army Medical Reserve Corps.

Dr Synnott was a member of the Essex County and New Jersey State Medical Societies, the American Medical Association, the American Therapeutic Society and the American Proctological Society. He was elected a Fellow of the American College of Physicians in 1923.

At the time of his death he was proctologist at Midtown Hospital, New York City, and Chief, emeritus, of the Medical Staff of St. Vincent's Hospital and had practiced Gastroenterology and Proctology for thirty-six years.

He was a member of the Immaculate Conception Church, Knights of Columbus and the American Legion

Dr Synnott's first wife, the former Miss Jane Agnew of Paterson, died in 1923. He married Miss Eleanor Southworth Hopkins in 1925, who survives him. He is also survived by a son, Paul A. Synnott of Port Chester, N. Y., a daughter, Miss Jane Synnott of Montclair, and a step-son, Ralph Hopkins, and a step-daughter, Miss Natalie Hopkins of Montclair.

Both the medical profession and the College have incurred a great loss in his untimely death.

CLARENCE L. ANDREWS,
Governor for New Jersey

ANNALS OF INTERNAL MEDICINE

VOLUME 10

OCTOBER, 1936

NUMBER 4

A COMMON LESION OF THE CERVICAL SPINE RESPONSIBLE FOR SEGMENTAL NEURITIS *

By EDWARD L. TURNER, M D, F A C P, and ALBERT OPPENHEIMER,
M D, *Beirut, Syria*

VON BECHTEREW,¹ Strumpell,² and Marie³ described many years ago some of the neurological problems associated with arthritic changes in the vertebral column. These early investigators observed variable clinical pictures in their cases of spinal arthritis and frequently found that there was no direct relationship between the arthritic change and the intensity of the neurological symptoms. Spastic, atrophic, or hypertonic motor changes and irritative sensory phenomena, or occasionally anesthesia and flaccid paralysis were present in certain of their cases with arthritic changes in the vertebral column.

In 1916 Nathan,⁴ who had observed numerous cases of spinal arthritis with neurological symptoms, induced experimental non-suppurative arthritis in animals in order to study the relationship between the pathological changes and the resulting symptomatology. Evidences were obtained of thickening of the periosteum of the vertebrae, thickening of the connective tissue in the region of the costo-vertebral joints and epidural exudate infiltrating the epidural areolar spaces. It was felt that these changes could lead to irritation and compression of nerve roots, the symptomatology depending upon the degree of nerve root involvement.

Williams and Yglesias⁵ studied the lumbar spine of a large number of cases suffering from sciatica and demonstrated a rupture of the nucleus pulposus with resulting collapse of the intervertebral disc and narrowing of the space between the fifth lumbar vertebra and the sacrum. Schmoil⁶ had previously described these findings in his studies of autopsied material. This condition caused a subluxation of the facets and a constriction of the intervertebral foramina. Subsequent irritation and compression of the fifth lumbar nerve roots produced the painful symptomatology observed in these cases.

* Received for publication June 23, 1936
From the Departments of Internal Medicine and Roentgenology, American University
of Beirut, Beirut, Syria

In 1934 Nachlas⁷ described a syndrome of pseudo-angina pectoris originating from demonstrable changes in the cervical spine. Each of the three cases described by him had a definite arthritic involvement of the lower cervical spine associated with thoracic pain. Irritation and compression of the cervical nerve roots secondary to these arthritic changes was felt to be the cause of the referred pain along the medial anterior thoracic and lateral anterior thoracic nerves. These nerves are motor pathways and supply the pectoralis major and minor muscles. Nachlas noticed that acute hyperextension and lateral bending of the neck produced a stab of pain referred to the region beneath the scapula or in the precordium of his patients.

Hanflig⁸ has recently described a group of 30 cases of pain in the shoulder girdle, arm and precordium due to cervical arthritis. He noted certain relatively characteristic clinical features of arthritis of the cervical spine, of which he placed rigidity and pain as the two most outstanding symptoms. He described these cases as frequent and as representing a large group of elderly individuals with symptoms commonly classed as neuritis. A successful method of treatment by traction and manipulation of the neck had been used on his patients.

This paper deals with a critical survey of over 50 patients observed by the authors during the past four years. It is presented because of the presence of a common finding in the cervical spine consisting of a distinct and clear cut narrowing of one or more of the intervertebral spaces.

Most of the patients in this group were over 50 years of age although two patients only 27 years old are included.

Pain in some part of the shoulder girdle, arm, hand, back, precordium or neck was usually the chief complaint though a few cases gave muscular weakness or inability to perform certain normal movements of the upper extremity as the most troublesome symptom. The pain described by patients was quite variable in degree and type. Some complained only of paresthesias while others experienced severe radiating pains. The location and types of pain observed in this group are outlined below.

- 1 Pain in one or both shoulders
- 2 Pain radiating down the arms (usually unilateral)
- 3 Pain on the radial side of the forearm and wrist
- 4 Tingling sensations in the fingers
- 5 Local painful spot between the scapulae
- 6 Pain under one scapula
- 7 Pain low in the neck (posteriorly)
- 8 Pain on turning the neck to one side
- 9 Precordial distress, diagnosed in several cases as aortitis or angina
- 10 Pain exaggerated by walking or riding
- 11 Inability to sleep because of pain in the recumbent posture
- 12 Pain accompanied by limitation of certain types of movement of the upper extremities

Pain was usually unilateral although it had shifted from one upper extremity to the other after months or years in several of the cases. In each of the instances where pain had shifted from its original site to the opposite side there has been a residual weakness of the muscles in the previously involved extremity. There was a simultaneous bilateral involvement in only a few of our cases. Most of the patients were not conscious of pain in the neck and, with two exceptions, did not give this as part of the chief complaint. With two exceptions there was no definite restriction of neck movements on passive or active turning of the head and neck in all possible directions. Whenever a patient complained of exaggeration of pain on walking, immediate, and in one case total, relief of this complication was obtained by having the patient wear soft rubber soles and heels. Pain over one shoulder was the most common of all chief complaints. Most of the patients had been suffering for months or years and had been subjected to various treatments. The story usually included a diagnosis of arthritis in the shoulder and treatment had been directed towards relief of the symptoms in that region. Salicylates had been used in some form by all of these patients. Only passing relief or no relief at all had been obtained from the use of salicylates. Some had been subjected to almost every conceivable form of treatment including ultra-violet light, diathermy, other forms of dry and moist heat, deep roentgen-ray therapy, ointments, liniments, massage and even cautery over the shoulder. Several patients had been treated for elevated blood uric acid because of a "uric acid diathesis." Unfortunately we found that no blood studies had been made on such cases prior to the use of cinchophen and allied substances. Blood studies in our laboratories in these patients failed to reveal an abnormal uric acid level. Obtaining little or no relief, these patients had become "medical drifters" going from one physician to another, even visiting the village cautery expert or some other irregular healer in an attempt to gain aid.

Next to pain the most common chief complaint was weakness in one upper extremity or an inability to perform certain normal movements. In some instances these disturbed movements were undoubtedly secondary to the pain elicited and were associated with some spasticity. In other cases they were the result of actual atrophic changes. Several patients complained of difficulty in writing. One patient, a nurse, found that she could no longer hold her pen properly and that it would slip from between her thumb and index finger when she started to write. In both male and female patients we observed numerous instances of inability to raise the arm in the type of movement involved in brushing or combing the hair. Placing a hat on or removing it from the head was a difficult procedure in some instances. Several women encountered great difficulty in fastening the buttons in the back of their dresses. In one instance a physician had difficulty in writing and in grasping the steering wheel of his automobile. The majority of these patients were unable to elevate the hand above the head in the position of abduction of the arm as in the Fascist salute. With two exceptions there

was no restriction of active or passive neck movements. Furthermore there was no observable limitation of movements of the cervical spine, when compared to normal individuals, on roentgen-ray examination in different positions.

Atrophy of the small muscles of the hand has been present in some instances. The hands of these patients may suggest an amyotrophic lateral sclerosis, syringomyelia or progressive muscular atrophy if both sides are involved. When the atrophy is unilateral the condition is suggestive of an accessory cervical rib—a possibility which can easily be eliminated during the roentgenologic study.

Although the types of spinal changes observed roentgenologically have been variable there has been one consistent finding in all of our cases. This has consisted of a narrowing of one or more of the intervertebral spaces in the cervical spine. If neurological symptoms existed in the patient and directed us towards examinations of the cervical spine this narrowing of one or more interspaces was found present regardless of whether we were dealing in addition with hypertrophic arthritis, infectious arthritis or with a traumatic displacement. Furthermore by a special technic developed by one of the authors (Oppenheimer) it was possible to demonstrate by roentgen examination an accompanying narrowing of the intervertebral foramen at the same levels. (The roentgen technic involved is being described in a separate paper.) This narrowing of the interspaces was present in some cases in which there was no roentgenological evidence of "spicule" or exostosis formation. In numerous instances marked hypertrophic changes, such as marginalipping of the vertebral bodies, were present but the narrowing of the intervertebral spaces also existed. These hypertrophic changes when present always involved the vertebral bodies on either side of a narrowed intervertebral space. One case, a young woman teacher 27 years of age with pain between the scapulae, showed arthritic changes between the fourth and fifth cervical vertebrae suggesting infectious arthritis. Another young woman of the same age showed a narrowing of the interspace between the fifth and sixth cervical vertebrae and a slight anterior displacement of the third and fourth cervical vertebrae.

The following case histories are given in some detail in order to illustrate the findings observed in this group of cases.

CASE HISTORIES

Case 1 V. D., a woman, 76 years of age. Complained of marked pain in the left shoulder with weakness of the right arm. The pains were greatly increased on walking or riding in a car. According to her statement pain began first in the right thumb about 17 years ago. This was followed by a dull pain in the whole right arm with definite limitation of movement so that it became difficult for her to comb her hair or to button her dresses at her back. The pain in the right arm gradually subsided after some years but never completely disappeared. Limitation of movement and residual weakness persisted in spite of this relief from pain. Seven months ago her left arm and shoulder became painful. Pain then increased in both shoulders.

and arms and eventually became so severe on the left side that she was unable to sleep comfortably. She experienced the greatest discomfort when lying on her back and soon learned that relief could be obtained by placing pillows under the head and bending the neck acutely forward. Marked weakness similar to that previously observed in the right arm began to develop in the left upper extremity. Combing the hair became so difficult that she had her hair cut off short to avoid the necessity of raising the arms to the head. The pain in the arms was invariably increased by walking or riding. When walking, the left arm and shoulder annoyed her so greatly that she developed the habit of holding the left hand in the right to protect the arm against undue movement. She had resorted to innumerable forms of treatment such as diathermy, hot compresses over the shoulder, liniments, ointments, massage locally and salicylates internally without relief.

Physical examination revealed no limitation of passive movement in the shoulder joints. She could not internally rotate the left arm and place the hand behind her back without eliciting marked discomfort. Elevation of the arm in abduction was impossible with either the right or left upper extremity. There was no atrophy of the shoulder girdle, arm or hand muscles. Passive and active movements of the neck were not limited and were not painful. There was no rigidity of the neck musculature.

Roentgen findings revealed that the intervertebral spaces between the fifth and sixth and sixth and seventh cervical vertebrae were definitely narrowed. There was a slight increase in bony density seen in the surfaces of these vertebrae. No exostotic formation, no rarefaction and no deformity of the bodies of the cervical vertebrae were observable. The diseased part was shifted slightly backward. Radiography of the entire spine was then made and no changes similar to those seen in the cervical spine were observed in the lower segments. The body of the twelfth dorsal vertebra was deformed, being flattened in its anterior portion. (Close questioning revealed an old fracture resulting from a fall off a ladder 42 years previously.) Roentgen-rays in different positions revealed no limitation of excursion of vertebral bodies in the cervical region during active movements. (Figure 1)

It is of special interest in this case to note that the patient observed relief from pain by bending her head forward. This movement relieved the pressure on the nerves in the region of the intervertebral foramen by temporarily widening the foramen. Because her pains were so aggravated on walking she was advised to replace her leather shoe soles with soft rubber soles and heels. This gave remarkable relief immediately from the discomfort on walking. Ultra short wave and deep roentgen-ray therapy over the cervical vertebrae has brought about marked improvement.

Case 2 A S, nurse, aged 54 years. The chief complaint was pain in both shoulders during the past three months. Her discomfort was most marked in the right shoulder. Certain movements, such as internal rotation of the arm and placing the hand in the middle of the back, caused great discomfort. Fastening a dress with the buttons or hooks in back had become impossible. At times her right shoulder felt quite numb. Three years previously she had noticed weakness in the right hand which was most troublesome when she was holding a pen. The pen would slip from between her thumb and index finger if she attempted to write for any length of time. About a year ago she noticed that the fleshy part of the right hand between the thumb and index finger was becoming sunken and flat. Recently the pain has been variable in intensity, sometimes radiating down the outer aspect of the right arm. On investigating her history closely it was found that 15 years ago she had had a very sudden attack of severe cervical pain a short time after a fall from horseback. At that time she was unable to turn her head to the left because of pain and it was necessary for a physician to administer several morphine injections for relief.

Examination of the shoulder joints revealed negative findings. Passive movements were free and unrestricted. She could not elevate the right hand above her head with the arm in abduction. She was unable to place the right hand in the

FIG 1 *Case 1* Showing narrowing of joint spaces between the fifth and sixth and sixth and seventh cervical vertebrae. Note the absence of lipping.

middle of her back over the sacrum and elevate the hand along the spine. This movement could be made passively although elevation of the hand along the vertebral column was more limited on the right side than it was on the left. The grip of the right hand was much weaker than that of the left. There was marked atrophy of

the soft tissues between the thumb and index finger of the right hand. No atrophy of the shoulder muscles on either side was present and the reflexes of both arms were present and normally active. There was no limitation of motion of the spine in the cervical region. The original diagnosis suggested on hearing her story and noting the atrophy of the small muscles of the right hand was an accessory cervical rib.

Roentgen findings revealed narrowing of the interspaces between the fifth and sixth and sixth and seventh cervical vertebrae. The bodies of the sixth and seventh vertebrae were flattened, their upper and lower surfaces irregular in contour and increased in bony density. There was moderate exostotic formation along the anterior borders of these vertebrae. There was no cervical rib. Roentgen diagnosis was atrophy of intervertebral discs with narrowing of the interspaces and hypertrophic spondylitis in the lower cervical spine (Figure 2).

This patient has obtained great relief from the pains in the shoulder and arm by forcible traction on the head. Relief was noticed following the first two treatments. All other methods of treatment were discontinued.

Case 3 V K, a woman, 27 years of age. The chief complaint was pain in the lower part of the back of the neck between the shoulder blades and over the shoulders (This was one of the two cases giving pain in the neck as the chief complaint). She had experienced recurrent pain in the back, shoulders and lower neck for several years. She felt that her troubles began following a diving accident and later a fall from a horse. There has been no radiation of pain down the arms. She has found it difficult to turn the head to the left when the pain was present.

Physical examination revealed a healthy young woman with no limitation of movement in the shoulder joints on passive or active manipulation. There was a localized tender spot over the second dorsal vertebra and limitation of movements of the cervical spine. Turning the head to the extreme right or left was difficult and painful. Hyperextension of the neck as in lifting the head when the patient was in a prone position was also very painful.

Roentgen findings showed a deviation of the cervical axis due to anterior displacement of the third and fourth cervical vertebrae. No bony pathologic lesion was seen within the bodies of these vertebrae. The intervertebral space between the fifth and sixth cervical vertebrae was narrower than the other intervertebral spaces. There was no demonstrable abnormality in the thoracic spine. The roentgen diagnosis was a definite abnormality in position of the cervical spine probably post traumatic with narrowing of one intervertebral space (Figure 3).

This patient was treated by traction on the head while lying in a supine position. The head was slowly turned from side to side while traction was exerted. Considerable relief was experienced following the first treatment. Physiotherapy in the form of traction and deep massage caudally over the upper thoracic spine while the patient was required to elevate the head and rotate it resulted in complete relief following three treatments.

Case 4 A K Z, a male banker, 53 years of age. The chief complaint was pain on raising the left shoulder, and a localized painful spot on the lower end of the right radius just above the wrist. The pain and limitation of movement in the left shoulder had gradually been increasing for the past several months. Discomfort was most marked during the night and early in the morning. It was difficult for him to raise the left arm when he put on his coat. Massage, heat, diathermy and baths had been used with no relief. He had also been informed that the pain in his shoulder was the result of an increase in the blood uric acid (diagnosed as a case of "uric acid diathesis") but he had obtained no relief from the use of atophan and other remedies. The left arm felt weak and heavy. For the past two weeks he had begun having a painful spot on the lower end of the right radius and felt that the

right hand was not as strong as formerly. His chief concern was a fear that he was developing a paralysis that would invalid him. One physician had frightened him badly by explaining that the pain in the left shoulder was the result of an aortitis.

FIG 2 Case 2 Oblique view showing actual narrowing of one of the intervertebral foramina

Examination revealed a well nourished male who was not acutely ill. There was no limitation of neck movement in any direction. It was impossible for the patient to elevate the left arm above his head. He could not internally rotate this arm and place the left hand behind his back. On relaxation it was possible to move the left

shoulder joint freely by manipulation of the arm. There was no local tenderness over the painful spot over the lower end of the right radius. Careful physical examination did not reveal any evidence of aortitis. Blood pressure was normal and the

FIG 3 Case 3 Showing deviation of the cervical axis due to anterior displacement of the third and fourth cervical vertebrae and narrowing of the interspace between the fifth and sixth cervical vertebrae

cardiac contour was within normal boundaries. He was advised to have a roentgen-ray examination of the cervical spine and for the sake of reassurance to have also a roentgen-ray examination of the chest.

Roentgen findings revealed a classical hypertrophic spondylitis of the lower cervical spine with lipping present on the anterior lips of the fifth and seventh cervical vertebrae. There was also a marked narrowing of the interspace between the fifth and sixth and the seventh cervical and first thoracic vertebrae (Figure 4)

FIG 4 Case 4 Showing hypertrophic spondylitis of the lower cervical spine with lipping of vertebral bodies and narrowing of the intervertebral spaces

The patient was advised to have a series of deep roentgen-ray and short wave treatments over the cervical spine combined with traction treatments. Although the patient was a well educated, intelligent individual he proved to be a skeptic and sought further medical advice. About a week later the patient returned quite worried over

the fact that further study had revealed that his heart was responsible for the pain in the left shoulder while the pain in the right radius was the result of a fracture. The patient was naturally greatly upset. We again advised him that his cardiac findings were normal and that the changes in his cervical spine were quite sufficient, in our

FIG 5 *Case 5* Showing narrowing of the interspace between the fourth and fifth cervical vertebrae with changes suggesting infectious arthritic involvement

opinion, to be responsible for the symptoms in the left shoulder. He was advised that we could find no evidence of a fracture in the right radius and that in all probability the pain complained of in this region was also referred pain secondary to the narrowing of the interspace in the cervical spine. As he was still not fully con-

vinced roentgenograms of both wrists were taken to demonstrate the absence of any bony lesion in either radius. He then consented to undergo neck traction treatment. The local pain in the right wrist disappeared following the first three treatments and there was marked improvement of the symptoms in the left shoulder within a week. Treatment was continued for two weeks and up to the present time (one month) there has been no recurrence of pain in either upper extremity.

Case 5 M. F., a woman teacher, 27 years of age. This patient was first observed by one of us in September 1932 at which time she complained of pain in the right arm and shoulder of nine months' duration. This pain had gradually increased in severity and was variable in its intensity. Sometimes the pain was so severe that it made her cry from discomfort during the night. Movements of the right arm, especially such movements as were involved in combing her hair, were exceedingly uncomfortable. She had also noticed that writing, sewing or knitting was associated with a feeling of weakness and fatigue in the right arm and hand.

Examination revealed no actual involvement of the shoulder joint and movements were quite free in all directions. There was no muscular atrophy of the shoulder or arm. There was limitation of movement of the neck laterally with muscular spasm when extreme lateral movements were attempted. A local pain spot was present under the right scapula.

Roentgen findings revealed that the intervertebral space between the fourth and fifth cervical vertebrae contained a few hazy calcifications. The anterior ligament connecting the bodies of these two vertebrae was calcified and the whole interspace was narrowed. The upper thoracic spine was normal. The changes in the cervical spine had the appearance of those seen in the infectious rheumatic type of arthritis (Figure 5). Search for foci of infection was instituted and the teeth carefully cared for. The patient experienced some relief from autohemoclysis and sterile milk injections intramuscularly. Salicylates had more effect in this case than they did in most of the other cases of our series. Traction on the neck, which was prescribed first, gave in this instance only partial relief.

DISCUSSION

In the five cases presented we have attempted to select histories demonstrating the different types of roentgen findings observed in our group of 50 cases. It will be noted that hypertrophic, post traumatic and rheumatoid changes have been included. Some of the patients showed no actual bone change of either the hypertrophic or rheumatoid type. All of the patients in this group had clear cut narrowing of one or more intervertebral spaces.

If one studies the relationships of the intervertebral foramina through which the nerves pass as they leave the spinal canal in the cervical region, it is quite obvious that narrowing of the interspaces between the vertebrae can and does change the diameter of these foramina. This narrowing can of course be doubly troublesome if there should happen to be exostosis formation around the foramen as well as atrophy of the intervertebral disc. Consideration of the relationships of these foramina also helps to explain why some patients have found it much more comfortable to sleep with the head propped forward since it will be seen that this position tends to widen the foramina while hyperextension increases symptoms because the borders of the foramina shorten the diameter in this position. Any inflammatory changes occurring around the nerves as they pass through these foramina

would also tend to aggravate the situation. Referred pain along the distribution of the fibers involved then takes place.

The middle and lower cervical regions were most commonly involved in our cases. This gives us a clue as to the cause of the frequent shoulder pain. The fourth cervical segment supplies the sensory innervation over the top of the shoulder, and the fifth cervical segment supplies the sensory innervation of the outer surface of the arm between the shoulder and elbow. The deltoid muscle is supplied by nerve fibers derived from the fifth and sixth cervical segments. Shoulder pain and limitation of certain types of shoulder movement should be an indication for study of the cervical spine. This is especially true of pains that are not associated with actual arthritic changes in the shoulder. One of the most common mistakes in regard to these shoulder pains is to regard them as indicative of heart disease.

It was pointed out at the beginning of this paper that most of our patients were over 50 years of age. If there is any indication of precordial distress or if the pain is limited to the left shoulder and arm it is rather natural to check on the state of the heart and large blood vessels. It must be remembered that these elderly individuals usually have aortic shadows more dense than those seen in younger people and that the diagnosis of an aortitis or aortic sclerosis as the cause of the referred pain should be made with caution unless very obvious pathology exists. On the basis of our observations we strongly advise that patients with shoulder pains or precordial distress be subjected to a fluoroscopic examination of the cervical spine as well as roentgen examination of the heart and great blood vessels.

The problem as to the actual etiology of hypertrophic arthritis of the spine is still unsettled. The observations made in our series of cases may help to explain the formation of exostoses seen in this type of arthritis. Since all cases in this group have shown a consistent narrowing of one or more interspaces we are led to believe that this narrowing may be the first change of importance that takes place in many or perhaps all of these cases that later develop hypertrophic spondylitis. The thinning of the intervertebral disc must greatly increase the trauma of the vertebral bodies especially along their margins. This traumatic factor alone could in time be responsible for sufficient irritation along the vertebral margins to produce the formation of exostoses and the lipping so frequently seen in this disease. This is being offered merely as a possible explanation but corresponds to the dog experiments of Compere and Keyes^{9,10}.

We are inclined to agree with Hanflig in regard to his statement that these cases are quite common. If they are kept in mind and actually looked for they will be seen from time to time in every physician's office. They constitute a group that is commonly misdiagnosed repeatedly and that frequently becomes medical "drifters" because of the absence of physical findings in the neck. This can be largely avoided by more careful history taking and roentgenological examination. Furthermore the question of referred pain in relation to changes in the cervical spine should be constantly

kept in mind when dealing with problems involving pain or disturbed movement of the neck, upper extremity and chest. Close questioning of these patients will frequently reveal severe trauma of the spine at some previous time, often many years earlier.

Some of these patients obtain marked relief by means of neck traction. Hanflig's technic of traction using a Sayres sling suspension with block and tackle arrangement is perhaps the most simple method. Manual traction and manipulation will give satisfactory results in some cases although it is exceedingly strenuous exercise for the manipulator. Some cases are relieved greatly by the use of ultra short wave therapy directly over the cervical spine. The use of soft rubber soles and heels is advisable for all patients suffering from pathologic lesions in the cervical spine.

Further discussion of the roentgen findings observed in this group of cases is being presented in a subsequent communication.

ACUTE PNEUMONITIS

By WILLIAM H. ALLEN, M.D., F.A.C.P., *Fort Sam Houston, Texas*

It is doubtful if there is anything in medicine presenting greater difficulty in classification than the so-called respiratory diseases. In every outbreak the problem arises when to cease the use of such terms as nasopharyngitis and acute bronchitis in order to adopt the equally indefinite one of influenza. One is confronted with the same difficulty in placing the pneumonias, though some progress is being made toward adoption of an etiological classification. It is with no wish to add to the prevailing confusion that we have found it useful to classify as acute pneumonitis a group of cases characterized by signs of respiratory infection, benign course, few physical signs, and roentgenographic evidence of a localized pulmonary involvement.

The dictionary gives pneumonitis as a synonym of broncho-pneumonia. Pathologically, this may be true but clinically and roentgenologically it represents a definite group, possibly a sub-group of the so-called broncho-pneumonias.

During the year 1935, there were admitted to the Medical Service of the Station Hospital, Fort Sam Houston, 2081 cases of respiratory disease. Of these, 53 were classed as primary lobar pneumonia, 16 as primary broncho-pneumonia, and 68 as acute pneumonitis. From the last I have selected 50 cases for analysis. It is doubtful whether this represents the true incidence of the condition as only in the more severe cases of respiratory infection were chest films made. As the diagnosis must be made almost solely by this means there appears to be no doubt that pneumonitis is generally overlooked. This is borne out by the paucity of reference to it in the literature.

Etiology This is uncertain but as all these cases occurred in the general group of acute respiratory infections it may be assumed that a filtrable virus with a secondary invasion by the ordinary bronchial tract organisms was the causative factor. While pneumococcus typing is carried out in all primary pneumonias, no effort was made to do so in the majority of these cases here reported. In a few, group IV pneumococci were isolated, in others, no pneumococci were found.

Due to the regulations governing admissions to our service, the great majority of the patients reported were young, adult males, but one female being included in the present analysis. The minimum age was 9 and the maximum 51 with an average of 25.5. We are unable to judge of the true age and sex incidence of this condition.

* Read by invitation before the Texas Club of Internists, San Antonio, Texas, February 21, 1935. Received for publication April 15, 1936.

From the Medical Service, Station Hospital, Fort Sam Houston, Texas.

Pathology As there were no deaths in this series or in others that I have seen no definite knowledge of the pathology exists The lung lesion may be visualized as an inflammatory and exudative process extending from the bronchioles into the alveoli over a localized portion of a lobe or lobes The involvement was predominantly of one or both lower lobes in 92 per cent

FIG 1 Pneumonitis extending from the right hilum

TABLE I
Lobes Involved

	Cases	Per cent
Right lower	18	36 0
Both lower	15	30 0
Left lower	11	22 0
Right all	2	4 0
Right middle	1	2 0
Right upper	1	2 0
Left upper	1	2 0
Both upper	1	2 0
	<hr/> 50	<hr/> 100 0

of our cases with the greater incidence on the right side. Taking the lungs as a whole, the right was involved in 44, the left in 24, and both in 32 per cent.

Symptoms On admission the patients complained of the usual symptoms of acute respiratory infection—cough, fever, malaise, and “cold in the head.” There was a noticeable absence of the ordinary symptoms of pneumococcus pneumonia, such as initial chill, sharp pain, and rusty sputum.

FIG 2 Pneumonitis of left lower lobe

When there was complaint of pain in the chest it was described as a dull aching or sense of fulness. In no case was there the stabbing pain of pleural involvement. This may be explained by the fact that the involvement was almost invariably central.

The maximum temperature was usually recorded within a day or two of the onset. Defervescence was commonly rapid though in a number of cases a low grade, irregular fever persisted for many days. The maximum temperature is shown in table 3.

TABLE II
Symptoms on Admission

	Cases	Per cent
Cough	43	86 0
Fever	35	70 0
Malaise	27	54 0
"Cold"	27	54 0
Pain or soreness in chest	15	30 0

103'-104'	7	14 0
104'-105'	5	10 0
	<hr/> 50	<hr/> 100 0

Physical Signs These were conspicuous by their absence. As shown in table 4, 36 (72 per cent) had fine or medium moist râles over the involved area, while 10 (20 per cent) had no demonstrable signs. In a large proportion no râles were found at the time of admission, these appearing from one to three days later. Impaired resonance was found in but 3 (6 per cent) and broncho-vesicular breathing in but 1 (2 per cent).

TABLE IV
Physical Signs

	Cases	Per cent
Fine or medium râles	36	72 0
Coarse râles	3	6 0
Impaired resonance	3	6 0
Broncho-vesicular breathing	1	2 0
Friction rub	1	2 0
No signs	10	20 0

The maximum leukocyte count was below 14,000 in 78 per cent of the cases, and in 54 per cent it was 10,000 or less.

TABLE V
Maximum Leukocyte Count

	Cases	Per cent
5000-7000	12	24 0
8000-10000	15	30 0

Roentgenological Signs Major Bowen of the Army Medical Corps, to whom I am indebted for the roentgenologic studies in these cases, has recently described the findings in influenzal pneumonitis as follows

Influenzal pneumonitis involves only a portion of a lobe, usually basal, though it has been seen in the upper lobes and involving more than one lobe without increase in symptoms. It extends outward from the hilus well into the parenchyma, occasionally reaching the periphery. The roentgen appearance is that of a confluent mottled fan or rounded area, usually of homogenous moderate density in the central portion, with the borders fading into the normal lung. It has the appearance of an exudative alveolar infiltration and is usually more localized and of more even density than the bronchopneumonias of childhood or than those which complicate adult diseases. The usual picture of broncho-pneumonia is a scattered mottling not confined to one lobe or sharply localized.¹

In the present series, 44 per cent showed a single area of pneumonitis while 36 per cent had more scattered infiltration. Eighteen per cent had two areas of increased density, usually involving both lower lobes.

TABLE VI
Roentgenologic Signs

	Cases	Per cent
Single area of pneumonitis	22	44.0
Two areas of pneumonitis	9	18.0
Scattered infiltration	18	36.0
No definite signs	1	2.0
	<hr/> 50	<hr/> 100.0

Complications These were rare. Three cases (6 per cent) developed acute maxillary sinusitis and one each, acute otitis media and urticaria. One case had a peritonsillar abscess with subsequent necrosis of the cervical lymph nodes, requiring operative intervention.

Prognosis There were no deaths in this series. The maximum period of hospitalization was 91 days for the case with peritonsillar abscess and necrosis of the cervical glands, the minimum was nine days, and the average 28 days. This average is in excess of what might be expected in a civil hospital due to the fact that a soldier is not discharged until he is able to return to full duty but it serves to indicate what may be considered the length of convalescence. In the majority of cases hospitalization was prolonged by weakness and the persistence of cough and râles after all other symptoms and signs had subsided.

A better idea of the duration of the disease may be gained from the days of fever as shown in table 7.

TABLE VII
Duration of Fever

Days	Cases	Per cent
1-2	4	8.0
3-5	15	30.0
6-8	12	24.0
9-11	7	14.0
12-15	4	8.0
16-20	2	4.0
Over 20	6	12.0
	<hr/> 50	<hr/> 100.0

Treatment This has been purely symptomatic. Emphasis has been placed on adequate nursing, free use of fluids, and a relatively high carbohydrate intake. Codeine has been used freely for the control of cough.

SUMMARY

1. Acute pneumonitis is used as the designation for a form of respiratory infection characterized by a benign course, few physical signs, and roentgenologic evidence of a localized inflammatory process in the lung.

2. In the absence of deaths the pathology is unknown but it is assumed to be an extension of an inflammatory process from the bronchioles to the alveoli with exudation.

3. The symptoms are those of a moderate to severe respiratory infection.

4. The diagnosis must be made by roentgenography.

DIVERTICULA OF THE STOMACH

By LAY MARTIN, M D , F A C P , *Baltimore, Maryland*

DIVERTICULA of the stomach are rarities. The average physician has had no experience with this abnormality, and this lack of experience is not limited to the clinical side of medicine, it is also found among the pathologists.

My interest in the subject was awakened by discovering a diverticulum of the stomach in a patient—a patient who wanted to know all about the condition. What should be the treatment—medical, surgical or none? What were the symptoms caused by the abnormality? Did it increase or decrease in size? What was the danger of perforation? How often should a re-examination be made? How often did it occur? What was the chance of malignant degeneration? As a result a study was made of the condition.

An exhaustive search through the archives of the History Department of the Johns Hopkins Hospital was unfruitful in revealing a single case diagnosed ante mortem. Not one was reported after laparotomy. Apparently none was reported by the roentgenologic department. The search was continued through the records of the pathology department and five cases were found. These and one living case are reported below.

CASE REPORTS

Case 1 A physician, aged 40 years, consulted me complaining of indigestion, bloating, distention and at times a gnawing sensation which was partially relieved by food. He was concerned about himself to the point of believing that he had a duodenal ulcer. Certain factors, to him of serious import, had come into his life and made him quite tense. His story was typically one of anxiety neurosis. On physical examination nothing remarkable was noted.

Fluoroscopic examination of his stomach showed an unusual condition. Barium flowed freely through the esophagus and the cardiac orifice. The stomach was in good position, the rugae well defined and regular, and the tonicity normal. To the mesial side of the lesser curvature, in the upper fundo-cardiac portion, was a spherical mass, which was mobile, not tender, clearly defined, of smooth regular outline. This was connected to the stomach by a narrow pedicle. Films made later by Dr. J. W. Pierson, convincingly demonstrated its patency and that it connected the barium filled sphere with the stomach. Hours after the stomach was freed of barium, the diverticulum remained visible. The patient finally solved his personal problems and the gastric symptoms abated. The diverticulum is still as noted above.

Since 1920, five cases of diverticulum of the stomach have been noted in the department of pathology of the Johns Hopkins Hospital. They are given seriatim below. In none of these cases does the clinical history give

* Received for publication January 6 1936.

From the Gastro-Intestinal Division of the Department of Medicine, Johns Hopkins Hospital and University.

any suggestion of the presence of the diverticulum and such symptoms as were manifest were located in other systems than the gastrointestinal

Case 2 A 39-year-old negro female

Anatomical diagnosis History of sudden convulsive death at operation under procaine anesthesia Operative wound in left thorax cardiac hypertrophy, ascites,

FIG 1 Showing diverticulum of the stomach soon after ingestion of barium sulphate

bilateral hydrothorax, edema of back, chronic passive congestion of lungs, liver and kidneys Diverticulum of stomach Mitral insufficiency

Macroscopic description The stomach is normal in size and contains a small

amount of semifluid food. The mucosa shows postmortem digestion. At the dome of the cardia, there is a small diverticulum about 3 cm across and bulging out about 2 cm. The musculature over this area is greatly thinned out and leaves practically nothing but the mucosa and serosa.

Microscopic description. All muscular coats except that of the mucosa disappear over a small area.

FIG 2 Showing diverticulum of stomach six hours after ingestion of barium sulphate

Case 3. A 59-year-old white male

Anatomical diagnosis. Acute and chronic verrucose endocarditis of aortic and mitral valves. Aortic stenosis and insufficiency, slight scarring of myocardium,

cardiac hypertrophy, chronic passive congestion of lungs and viscera, clubbing of fingers, edema of ankles, mural thrombosis pulmonary emboli, infarcts, and edema. Generalized arteriosclerosis, old scars in kidneys, prostatic hypertrophy, slight hypertrophy of bladder muscle. Dental caries. Diverticulum of stomach. Papillary cystadenoma of kidney. Thrombi in prostatic plexus.

Macroscopic description Near the cardiac orifice the stomach wall is thinned out over an area of about 2 cm in diameter so that a little pouch is formed.

Microscopic description Sections of the stomach taken through the pouch show normal serosa and mucous membrane. The muscular layer is scant.

Case 4 A 60-year-old white male.

Anatomical diagnosis Hypophyseal tumor pressing on optic chiasm with atrophy of right optic tract and nerve. Calcified area on surface of right upper lobe with fibrous pleural adhesions. Caseous tuberculous lymph nodes along trachea and hilum of right lung. Disseminated tubercles in liver, lungs, spleen, kidneys. Obesity. Diverticula in pylorus.

Macroscopic description Just proximal to the pyloric valve there are two diverticula measuring 1 cm in diameter and 1 cm deep, over which the mucosa appears to be intact. Dr. MacCallum: "At the pylorus there is a sacculation with complete lining of mucosa."

Microscopic description The walls of the one diverticulum seen are normal.

Case 5 A 16-year-old negro female.

Anatomical diagnosis Acute necrosis of liver, small liver, jaundice, hemorrhages into endocardium, puerperal uterus, diverticulum in pyloric position of stomach, accessory pancreas. Fresh ulcers in duodenum, diffuse enlargement of thyroid. Calcified vessels in corpus striatum.

Macroscopic description Stomach—about 1 cm from the pylorus there is a small diverticulum in the stomach wall with an opening measuring 5 mm in diameter. It is about 1 cm deep and there seems to be a palpable little tumor at the end of the diverticulum. The lining of the little cavity seems to be normal pale mucosa. There is also a duodenal ulcer.

Microscopic description Stomach. There are two sections which show the stomach. The opening of the small diverticulum is missed. The section one was cut further to show it if possible. However, one shows the space in the wall of the stomach and at the base the little nodule which turns out to be for the greater part made up of gland tissue. There are a few areas of pancreatic tissue.

Case 6 A 28-year-old negro female.

Anatomical diagnosis Encapsulated caseous tubercles in lungs, hyaline and caseous tubercles in tracheal lymph nodes. Disseminated tubercles in spleen, liver, kidneys, intestines and lung. Tuberculous meningitis. Infarcts in spleen, purulent tonsillitis, lobular pneumonia. Cyst in left ovary with hemorrhage. Scarring of pancreas. Syphilis (positive Wassermann). Diverticula of stomach.

Macroscopic description The fundus of the stomach is thinned out, and on the ventral surface of the greater curvature, near the cardiac end, four shallow excavations are seen. Peculiar punctate excavations measuring less than a millimeter, are generously scattered in the mucosa near the cardiac end of the greater curvature, more posterior than the larger ulcers. There is a diverticulum lined with normal stomach mucosa near the pyloric end of the fundus.

Microscopic description The mucosa, muscularis, muscular layer and serosa are intact.

DISCUSSION

The subject about to be discussed offers one of the best examples of that common fault of the medical historian, i.e. the acceptance of previous au-

thors' interpretations of the writings of others. The writers who have made any attempt to outline the history of our knowledge of gastric diverticula all refer to Helmont as being the first to see and report the finding. Voigtel is the authority generally cited for first mentioning Helmont. Those who do not mention Voigtel assert that Helmont in 1804 reported the first case.

To explain the continued reiteration of this inaccuracy, we may best start with the report by M. Fournier³ in 1774. He performed an autopsy on a former patient, whose clinical course had been completely mystifying to him. His description of what he observed on section is of no immediate interest to us until he says that the stomach was filled with numerous foreign bodies such as pieces of iron, wood, etc., and he writes "La forme de l'estomac était un quarre long. On y distinguait aisement quatre faces chacune de quatre pouces de largeur. L'ayant ouvert nous y trouvâmes toutes les pièces détaillées ci-après dans le rapport et tellement arrangées que l'on aurait dit qu'une main adroite les eut placées chacune de façon qu'elles eussent occupées le moins de place possibles." At no point in his article is there any reference to a sac or a diverticulum. In 1804 Voigtel⁴ referred to Fournier's patient, and commented upon the numerous articles swallowed by him. In describing the pathological findings (on page 512) he says "Im Schlunde fand man ein grosses Stuck Holz im Magen aber, innerhalb einen besondern Sack." Surely a misrepresentation of the facts as reported by Fournier.

Another factor which has apparently helped confuse the unwary was Voigtel's⁴ description of a duodenal diverticulum on page 504, under the general subject of *Hydrops Ventriculi*. He writes "In der mitte des Pfortners hing ein mit Wasser gefullten Sack, der eines Fingers lang und einen Zoll dick war, und sich in der Zwolfingerdarm erstreckte." Citing previous references to the subject he refers to page 154 of Moebius'² book, which was published in 1661. Here the author may be quoted "*Hydrops Ventriculi* menit Lazari Riverus in observat communie p. 364 in quo tantus tumor ejus ut ex aperto nonaginta librae aquae effluerent."

It so happens that on page 137 of this same volume of Moebius there is a reference to Helmont "*sacculum ventriculi annatum et lapidibus repletum conspexit Helmont*." Not only does Voigtel not refer to Helmont but his reference to Fournier is incorrect, besides that the diverticulum he himself observed and described was connected with the duodenum.

Another mistake which has been carried on down in the literature is in regard to a gastric diverticulum alleged to have been described by Vasquez⁵ in 1859. A soldier died some time after being badly jarred. On section there was revealed "existencia sobre su parte superior y lado derecho de enorme saco, ciego, al parecer, mas en comunicacion con el esófago por pequenos aquejeros que a modo de regadera daban paso a las líquidas bebidas de que estaba llena su cavidad, y cuyas paredes de mas de un pulgada de grosor ostentaban en su superficie esterna diversas másticos desde el violado

al claro, propio de las membranas " In this instance there was a traumatic diverticulum of the esophagus, not of the stomach

In spite of the rarity of the abnormality there is quite an amount of literature on the subject, and to avoid the possible continuation of the errors noted above the information presented below has been taken from the original reports. The compiled data on the 103 uncomplicated pulsion diverticula are presented in table 1, and the cases are arranged in their order of publication. Besides this number, the other 22 more or less complicated cases are reported in their turn.

Reports are available from many countries. The earliest authentic case I have found is that of Thomas Baillie,¹ who writes "A part of the stomach is occasionally formed into a pouch by mechanical means, although very rarely. I have seen one instance of a pouch being so formed, in which five halfpence had been lodged. The coats of the stomach were thinner at that part, but were not inflamed or ulcerated. The halfpence had remained there for some considerable time, forming a pouch by their pressure, but had not irritated the stomach in such a manner as to produce inflammation or ulceration." His report has been followed by others, at first, as one might suspect, mainly from Germany. These early cases were noted at autopsy and, although many were reported in full and with suggestions as to etiology and reasons for their position, they were incidental findings. They have been found at all ages. Broman²⁹ and Pernkopf⁷¹ each found one in an embryo and Sinclair⁷³ reported a four months old child who was operated upon for the same condition. The majority of these cases were first observed when the patients were in their thirties, forties and fifties. It has been the habit of most observers to state that the abnormality was most commonly seen in women. Of the 103 cases reported, 54 occurred in women.

DESCRIPTION OF THE ABNORMALITY

There are two general types of diverticula of the stomach.

1 *Pulsion*. This includes the congenital group and also the cases which result from such congenital malformations as a gastric muscle hiatus, a localized absence of gastric muscle, or simply a local weak area of gastric muscle. In the latter sub-division, a sufficient increase of intragastric pressure might distend the weak spot until a pouch or diverticulum was formed.

2 *Traction*. This includes such pouchings, folds, protrusions, niches, etc., as are brought about by disease process (infections, neoplasm) in the gastric wall, or by any process without the gastric wall which will cause it to protrude in any of the conditions noted above.

The diverticula reported in this paper were all of the pulsion type.

POSITION

The most common location for the pulsion type of diverticulum is near the cardiac opening of the stomach. Most anatomists state that in this region the stomach musculature is poorly developed.

TABLE II
Tabulation of Some of the Characteristics of 103 Uncomplicated Pulsion Diverticula of the Stomach

	Mucosa Thinned Muscles		Intact	No Serosa Note only	Cardiac		Lesser Curvature Mid Portion		Greater Curvature Mid Portion		Miscel	Male	Female	Not Stated	Pres- ent	None	Question- able	No Note
Condition of Wall of Diver- ticulum	16	23	6	8														
Position of Diverticulum					63	11	14	5	4	6								
Sex of Patient												43	54	6				
Symptoms															50	16	16	21

From table 2 it is evident that 61 per cent of the diverticula of the stomach are situated within the radius of a few centimeters of the cardia. The other 39 per cent are distributed most frequently along the lesser curvature. They have also been found to occur along the greater curvature and on the anterior and posterior surfaces of the fundus of the stomach. In the living case reported in this paper, and in which the diagnosis was made by roentgen-ray, the diverticulum was situated on the lesser curvature some distance below the cardiac orifice.

HISTOLOGY OF THE WALLS OF THE DIVERTICULA

Diverticula of the stomach may be classified under three headings in respect to the construction of their walls

- 1 Those consisting of one or more layers of gastric tissue,
- 2 Those consisting of gastric tissue plus pancreatic cells,
- 3 Those consisting of tumor cells plus more or less gastric tissue

1 *Various Gastric Layers* In far the greater number of diverticula the stomach walls contain only gastric tissue. From case to case there may be a wide range of difference in the construction of the individual wall, it may consist of anything from gastric mucosa with a covering of serosa to a wall which includes normal muscular and mucosal layers. In table 2 the construction of the wall has been tabulated as intact, muscle thinned with mucosa and serosa present, and mucosa and serosa only. Of the 56 cases in which the diverticulum was examined and described 16 had intact walls, 23 had thinned muscular layers, and six had walls which consisted of mucosa and serosa alone. The other eight were not described.

No case has been included in which the serosa had been distorted to the extent that the diverticulum might be of the traction type. The two diverticula found in embryos were found to be lined with normal mucosa and to have a musculature like that of the rest of the stomach. This was also true in the case of the infant of four months upon whom Sinclair operated. In two of the cases in my series there was a complete absence of musculature over part of the diverticulum. This was demonstrable macro- and microscopically.

A number of investigators have endeavored to further define the characteristics of the two sub-groups (congenital and acquired) of the simple pulsion type. They would classify as congenital those which contain all the layers of the gastric wall. Those which contained thinned musculature, they would classify as acquired. Several of them believe that those whose walls consist of mucosa and serosa only should be called herniations.

It is noteworthy that although there is a great variation in the thickness of the gastric musculature, the mucosa has been found, with one or two exceptions, to be similar to that noted over the remainder of the stomach.

2 *Pancreatic Inclusion* One case of this type is presented in my series

and 14[†] others have been culled from the literature. In only one instance was such a diverticulum found near the cardia, in this patient⁷ there were two diverticula, one as noted and the other near the pylorus. In the other patients the pouch was near the pylorus and (except in three instances) on the lesser curvature. The wall of these diverticula always consisted of the normal gastric layers and the island of pancreatic tissue was usually found at the peak. There seems little doubt that these represent congenital abnormalities. Broman²⁹ feels that they are simply the dilated excretory ducts of hypertrophied pancreatic islands whose acini have not been able to develop normally.

The only two cases which were found at operation were reported in a general article by Moynihan⁶⁷. The finding was accidental, for he was operating for duodenal ulcers. All the others were noted at autopsy. My case is the only one reported in recent years.

3 *Tumors Benign or Malignant* Adenomyoma^{39, 91, 49, 71} have been found in the walls of gastric diverticula on four occasions, carcinoma^{40, 31, 38} thrice and fibrosarcoma once⁹¹.

SIZE AND SHAPE OF DIVERTICULA

As might well be suspected, the diverticula are of various shapes and sizes. The openings may be small and lead through a narrow pedicle into a considerably enlarged sac. Again the diameter of the opening may be the largest dimension, so that the diverticulum assumes a pouch-like appearance. If the sacs do not retain barium, the diverticula will, of course, be undiagnosed roentgenologically, and they may well be missed at operation. The diameters of the sacs of the original cases herein reported vary from 1 by 2 cm. to 5 by 6 cm. This corresponds to the variations of most of the reported cases, although some of them are larger.

The largest was measured by Stolz and Hickel⁴⁸ as 8 by 10 by 20 centimeters. It was removed at operation. Kleime¹² also reported an operative case with a diverticulum the size of his fist. In both, the walls were reported as normal and the pedicle was inserted in the prepyloric region.

Two groups of investigators^{80, 84} cite instances in which small openings of gastric diverticula were seen via the gastroscope.

ROENTGENOLOGIC DIAGNOSIS

Since the use of roentgen-rays for diagnosis of gastric abnormalities, there has been a marked increase in the number of reported cases of gastric diverticula. It is in the past 15 years that the majority of the cases have been described. From the early days attention has been called to the difficulty of making the distinction between the pulsion and the traction diverticulum and especially Haudek's niche.

[†] Thelemen,²⁴ Glinski,¹⁹ Klob,⁶ Gegenbauer,⁸ Wagner,⁷ Nauwerk,³⁹ Falconer,²⁶ Weischelbaum,⁹ Vigi and Gamberini,⁵³ Muller,²¹ Moynihan,⁶⁷ 2 cases, Heubel,¹⁰ Gardiner,²⁰ Merkel,²³ 2 cases.

It is interesting to note that the first roentgen-ray demonstration of gastric diverticulum was by Brown³⁵ in 1916. Before operation it was considered to be the defect of a gastric ulcer. At operation it was recognized as a pouch-like diverticulum and was invaginated. Four years later Mellon, et al⁴⁰ noticed a defect which was called carcinoma. At operation a diverticulum was found, and section of its mucosa, they state, showed precancerous changes. It was in 1923 that Akerlund⁴² elevated the technic of roentgenologic diagnosis of this condition to its present high plane. Now, under properly controlled conditions, an experienced observer is not apt to label some other condition as a diverticulum. Failure is more liable to occur on the negative side, i.e. diverticula when small, or in unusual positions may not produce recognizable shadows.

Akerlund laid down certain essential requirements to be met before a clear cut decision could be made. The sac must be mobile, it must be loose and unattached to extra-gastric surrounding tissue and organs, the shadow must be well defined, smooth, regular and must be noted from various angles. Generally there is no tenderness.

The cardiac end of the stomach is a loose, rather flabby tissue and occasionally it overhies the fundus, so that to the inexperienced observer the bizarre examples of juxtaposition are puzzling. This type of residual must not be confused with diverticula. It is possible that this is one of the bases for a number of alleged mistaken roentgenologic diagnoses of diverticula of the stomach. I say allegedly mistaken because their absence was inferred from the fact that they were not found at operation. However, as noted in the case report, it seems quite likely that some of the pouch-like type of diverticula may easily be missed at operation, particularly so when they occur in such surgically inaccessible regions as near the cardiac orifice of the stomach.

In spite of the fact that a number of roentgen-ray diagnoses have been corroborated at operation and that numerous undiagnosed diverticula have been seen at autopsy, there is a large school of skeptics. The first of these was de Quervain⁴⁴. He has been followed by Schlesinger,³⁷ Guillot,⁴⁵ Zoltan,⁴⁶ Muller³⁸ and a number of recent Italian investigators. Especially vehement among them are Anziolotti,⁵¹ and Taddei.⁴⁷ The former has written a long review on the subject which contains much of interest and a great deal not germane. It would seem that the only justification for this school is that it draws attention to the care necessary for diagnosis. It also illustrates the need for correct historical approach since its exponents are unaware of the proved cases in the literature.

SYMPTOMS

Many investigators have reported instances in which symptoms were accredited to gastric diverticula. In a number of these studies, diagnosis was made by roentgen-ray. While under properly controlled conditions this is

a satisfactory procedure, it does not rule out other complicating factors which might readily be the basis for the symptoms. Other cases have been reported in which operative procedures have been carried out on patients with definitely known complicating disorders. In some of these instances the diverticulum was found during the routine surgical examination of the stomach.

The only acceptable method for establishing a basis for the belief that diverticula might cause symptoms is by surgery. In uncomplicated cases the disappearance of symptoms, following diverticulectomy, would be fairly conclusive proof if a sufficient number of patients were operated upon. In table 3 is a compilation of the 28 operations performed on patients with ap-

TABLE III
Records of Some of the Findings on 28 Patients before and after Operation

Ref	Author	Age of Patient	Symptoms	Position of Diverticulum	Result

48	Stolz	48	+	prepyloric	cured

parently uncomplicated gastric diverticulum. It shows that an impressive number, 64.3 per cent, became symptom free after operation. Three of the operators were unable to locate the diverticulum. In 18 per cent of the cases where symptoms were accredited to the abnormality, no note was given as to the effect of the operation. In the cases of only two of the patients was there doubt that the symptoms were caused by the diverticulum. In all but six of these cases the diverticulum was located in the fundic or pyloric regions.

In a few cases, notably those of Huist and Briggs,⁵⁴ symptoms disappeared after the patients learned to empty their diverticula by postural drainage. Bell and Golden⁸⁷ also state that this procedure might be of assistance.

Judging from the reported cases, the symptomatology is varied and apt to be vague. The most general complaint is indigestion, i.e. gas, distention, eructation and, at times, pain coming on some time after meals. A considerable number of the patients complained of a gnawing sensation and a hunger pain with relief by food which was suggestive of peptic ulcer.

Since it may now be taken for granted that diverticula do cause symptoms, it is quite likely that the symptoms of a number of those patients, whose diagnosis was made by roentgen-ray, were caused by the diverticulum. Many of the cases were carefully studied, and an analysis of the impressions of the investigators shows that in 49 per cent of the cases the opinion prevailed that there was a direct connection between symptoms and sac, and that in 16 per cent of the cases such a connection was held to be questionable.

In table 2 it may also be seen that in 21 cases (about 20.3 per cent) there was no statement as to symptoms and in only 16 cases (about 15.5 per cent) did the writers explicitly state that there were no symptoms. Of the former, 17 were noted in autopsy material in which the diverticulum was an incidental finding and a careful review of the clinical symptoms was not given. Of the latter there are a number of cases diagnosed by roentgen-ray in which the diverticulum was also a chance finding.

Bleeding is not a rare complication, having been noted on eight occasions^{56, 91, 90, 35, 42, 83, 73, 30}. Surgery has been utilized in six of them. In one, evidence of bleeding from a diverticulum was found post mortem. In the other instances it ceased.

It should also be noted that in all the literature no case of rupture of a gastric diverticulum has been reported.

MISCELLANEOUS DETAILS

It may be of interest to recount some of the other peculiarities met with in this abnormality. Four times^{91, 56, 45, 82} it has been noted that there were two or more diverticula of one stomach. In the same number of instances^{12, 26, 91, 14} it has been associated with a diverticulum of the duodenum. On three^{14, 82, 91} occasions a gastric diverticulum was noted in patients with diverticula of the colon.

The combination of diverticulum and ulcers has been commented upon by a number of writers. Kleine,¹² Boreszky,³³ Schlesinger³⁷ and Jones²⁷ feel that diverticula may result from a gastric ulcer when internal pressure reaches a certain height. However, the great majority of diverticula have not been found in association with ulcers. Consequently, whereas the symptoms of uncomplicated gastric diverticula are often suggestive of peptic ulcer, it must not be forgotten that ulcers may be associated with the ab-

normality In the articles reviewed the association of diverticulum of the stomach and peptic ulcer has been encountered 10 times ^{77, 85, 37, 42, 91, 48, 12, 14} Three of the cases were reported by Kleme ¹²

TREATMENT

Treatment of this abnormality, as in most medical problems, is a matter of judgment Probably a number of diverticula have been observed in the study of a patient suffering from neurosis, though the defect was giving no symptoms The living case reported above is an example of this situation and it would be clearly erroneous to consider this abnormality as a cause of his symptoms It is questionable if diet or medication has any useful field of application here However, in certain instances, where there is reflex irritability, some relief may be obtained by smooth food and by belladonna Obviously, if there are no symptoms the conditions should be left alone, for let it be recalled that no report of perforation has come to light Consequently, there is no necessity to make an immediate decision between medical and surgical treatment

The question of carcinoma developing is of course to be considered Here it may be restated that only a minimal number of such cases has been observed Therefore the risk is apparently but slight Instances have been reported in which relief from symptoms was produced by postural drainage, but this procedure would be of service only in those cases having a sufficiently broad pedicle

As noted above, 24 cases have been reported in which the symptoms of the patient have justified operation and in which postoperative relief was obtained Consequently one should not hesitate to use surgery if the occasion warrants it

A STUDY OF FOUR CASES OF ACQUIRED ARTERIO- VENOUS FISTULA BY MEANS OF THORO- TRAST ARTERIOGRAPHY

By WALLACE M. YATLER, M.D., F.A.C.P. *Washington, D. C.*

ARTERIOGRAPHY is a valuable adjunct to the methods of investigation of vascular disease of the extremities. Thorotrast,† a 25 per cent stabilized colloidal solution of thorium dioxide, is a very satisfactory medium for this procedure. This radiopaque contrast medium was used first for hepatosplenography^{1,2}. It has been used without apparent serious immediate or remote ill effects by a number of investigators in this country^{3,4,5} in spite of its non-acceptance by the Council on Pharmacy and Chemistry of the American Medical Association⁶. For several years it has been used extensively both abroad and in the United States for arteriography of the extremities^{7,8,9,10,11,12,13}. The amount necessary for arteriography is much less than the 75 cc often employed for hepatosplenography. The use of this amount for the latter purpose in most of 175 cases by Rigler, Koucky and Abraham⁵ over a period of three and a half years and in 200 cases by Yater, Otell and Hussey¹⁴ over a period of nearly five years has not been found to be associated with latent radioactivity, the most important ill effect contemplated. For roentgenographic demonstration of the vascular system of an upper extremity an average of 10 cc and of a lower extremity an average of 20 cc are usually sufficient. These relatively small amounts are certainly devoid of any possible latent ill effects.

TECHNIC OF ARTERIOGRAPHY

With a moderate amount of experience the brachial artery in the antecubital fossa (the needle pointed toward the axilla) and the femoral artery in Scaipa's triangle (the needle pointed toward the pelvis) can readily be entered through the skin with a venipuncture needle (18 gauge, 2 inches long). The skin and tissues around the artery are first anesthetized under aseptic conditions with some local anesthetic, such as 1 per cent novocaine. The artery is punctured by the needle attached to a syringe containing the Thorotrast, the extremity being in position for the taking of the first roentgenogram. When the point of the needle is within the lumen of the artery bright red blood flows forcibly into the barrel of the syringe and pulsates therein until the vessels proximal to the needle are occluded. In the arm the cuff of a sphygmomanometer is usually used for this purpose, the cuff being inflated above the systolic pressure. In the thigh an assistant can

* Received for publication May 9, 1936

From the Georgetown University School of Medicine and the Gallinger Municipal Hospital, Washington, D. C.

† Manufactured by the Heyden Chemical Corporation of New York

easily occlude the femoral artery by digital pressure of the vessel against the pubic bone. The Thorotrast, at room temperature or previously warmed, is then injected with moderate speed into the artery and the needle withdrawn. The first roentgenogram, usually anteroposterior, is taken almost at once without allowing blood to flow into the arteries.

If the upper extremity is to be studied the forearm and hand, palm upward and fingers slightly separated, are posed on one half of a 14 by 17 inch roentgen-ray film, the other half being covered by a lead shield. After the first exposure is made the extremity is shifted to the other half of the film. The sphygmomanometer cuff is rapidly deflated to the height of the diastolic pressure and four beats are allowed to pass into the forearm, after which the cuff is rapidly inflated to a point above the systolic pressure. The second exposure is then made. The first exposure usually shows the main arteries of the forearm with a few of their branches and the palmar arches, the second shows some of the main arteries of the forearm, the palmar arches, some of the digital arteries and often some of the veins.

If the lower extremity is to be studied the lower two-thirds or more of the thigh and the upper one-fourth of the leg are posed on half of the film. After the first exposure the film is shifted down to include on the unexposed half the leg and foot either in the anteroposterior position or in the lateral position with the leg somewhat flexed. Five beats are then allowed to pass into the extremity, after which the occlusion is re-applied and the exposure made. The first exposure usually shows well the femoral artery and a few of its branches, the popliteal artery and the first part of its main branches, the second shows the main arteries of the leg with some of its branches and the main arteries of the foot.

The following roentgen-ray technique is satisfactory. Tube distance 30 inches, $\frac{1}{2}$ millimeter aluminum filter, high speed screens, 100 milliamperes, 2/10 second, voltage varied according to thickness of the part (3 cm, 46 K V P, 4 cm, 47 K V P, 5 cm, 49 K V P, 6 cm, 52 K V P, 7 cm, 55 K V P, 8 cm, 57 K V P, 9 cm, 59 K V P, 10 cm, 62 K V P, 11 cm, 65 K V P, 12 cm, 68 K V P, 13 cm, 71 K V P, 14 cm, 74 K V P, 15 cm, 76 K V P).

One of the most important difficulties occasionally encountered is spasm of the artery consequent to its puncture. To avoid this drawback I make it a custom to inject the contents of an ampule of Spasmalgim* intravenously about 15 minutes prior to the arterial puncture. This procedure also relieves the nervous patient's apprehensiveness.

When properly performed, the injection of the Thorotrast is made with light pressure. If the injection requires undue pressure the needle is not in the lumen of the artery. Even if the medium is injected into the tissues about the artery or into the wall of the vessel, however, no serious damage

* Each ampule contains Pantopon 0.011 gm, papaverine hydrochloride 0.022 gm and Atromal (sulphuric acid ester of atropine) 0.001 gm. It is prepared by Hoffmann-LaRoche, Inc.

is done. There are, however, pain, redness and local heat, which subside in a very few days with the use of hot, moist compresses.

USES OF ARTERIOGRAPHY

Arteriography has been used mainly to assist in determining the kind of vascular disease, the location of occlusions and the extent of the collateral circulation^{12, 13, 15}. Consequently, most of the cases have been instances of vascular disease associated with trophic changes or gangrene. Some cases have been reported, however, of aneurysm and arteriovenous fistula. The latter have been rare. Horton has reported a case of acquired arteriovenous fistula¹⁶ and one of congenital fistula¹⁷. Frick and Levy¹⁸ have reported two cases of the congenital form.

ACQUIRED ARTERIOVENOUS FISTULA

The acquired form is usually due to a gunshot or stab wound, more often the former. There is usually one fistula, but occasionally there are more. The penetrating body must go through both the artery and the vein. A hematoma forms about the vessels, soon stopping the hemorrhage. Adhesions develop about the outer surfaces of the vessels, closing their lateral wounds, but the blood from the artery, being under much higher pressure than that in the vein, passes through the fistula between the artery and the vein and prevents closure of the adjacent openings. Thus, the individual bleeds constantly into the veins of the extremity. The fistula is usually a direct one, the formation of an aneurysmal sac between the artery and vein being uncommon. Medium-sized and large vessels are usually affected, since the penetrating object must pass through them without completely severing them.

A small fistula is well borne by the organism, necessitating little readjustment, but a large one involving a large artery and vein calls forth compensatory mechanisms in order to overcome the effect of the constant tendency to a diminution of arterial blood volume and to provide sufficient blood flow through the affected extremity. The heart enlarges and beats faster, the pulse pressure increases, due mainly to a drop in the diastolic pressure, and the total volume of blood increases. When the fistula is closed by compression the pulse rate suddenly drops to normal (Branham's bradycardiac sign¹⁹), the blood pressure becomes raised, and the cardiac shadow contracts. Because of the severe strain placed upon the heart, congestive failure may eventuate.

The local effects consist in dilatation of the vein involved and the proximal part of the artery. The tributary veins become dilated and tortuous. The superficial veins of the extremity become prominent. The blood pressure in the veins of the extremity approaches that of the arteries, and the oxygen content of the blood in the veins becomes practically arterial. The veins may actually pulsate. The surface temperature over the fistula is

usually increased, that distal to it decreased. The limb distal to the fistula is often increased in girth due to venous engorgement and edematous infiltration and hypertrophy of the subcutaneous connective tissue with atrophy of the skin and skeletal muscles. Trophic changes are prone to occur distal to the fistula. Since the flow of blood through the arteries distal to the fistula is greatly decreased, the veins take over the function of the arteries in nourishing the limb, but there is difficulty in the return of deoxygenated blood from the capillaries. Partial anoxemia of the tissues results. If these tissues are even slightly injured the normal inflammatory reaction of repair is feeble or absent, and progressive ulceration or gangrene supervenes.

A loud hum with systolic accentuation is heard with the stethoscope over the fistula and in its neighborhood and is transmitted down the course of the veins, often to the tips of the fingers or toes. A thrill is palpable also over the fistula and may be transmitted a short distance along the vein.

There is usually no difficulty in differentiating between a simple aneurysm and an arteriovenous fistula, since the physical signs mentioned above are lacking except perhaps for a less intense systolic murmur, and a thrill if present is less marked. Trophic disturbances are not so common or severe. The venous phenomena do not occur, and the oxygen content of the blood in the veins is not increased.

The four cases reported below illustrate the phenomena described. They also show the value of arteriography in cases of arteriovenous fistula. The exact site of the fistula may be determined, its size estimated, and the mechanism of blood flow through the extremity explained. The extent of the collateral circulation, however, can not thus be gauged.

CASE REPORTS

*Case 1 Small fistula between the ulnar artery and vein.** A negro boy, aged 15 years, was sent to the Gallinger Municipal Hospital on February 26, 1933 because his heart had been found to be moderately enlarged by a physician in the syphilis clinic, where he was being treated because of a positive blood Wassermann reaction. His health had always been good except for measles, mumps and chickenpox. Five months previously he had been wounded in the right arm by a shotgun. His arm had become swollen and bluish immediately afterward, but these signs had gradually disappeared without leaving any disability of the extremity. Physical examination was essentially negative except for the heart and the right arm. The heart was moderately enlarged, the apex beat being 8.5 cm from the midsternal line in the fifth left intercostal space. There was a soft systolic murmur at the apex and a higher pitched systolic murmur at the base. The second aortic sound was accentuated. The right arm and forearm were visibly larger than the left. The length of both arms was 48 cm. The circumferences of the arms at various points were as follows: Arm, 7 cm above olecranon process 22 cm left, 23.8 cm right. Forearm just above wrist 15.2 cm left, 16 cm right. Hand below thumb 20 cm left, 20.4 cm right.

A number of small scars in the antecubital fossa and its neighborhood were present where the buckshot had entered. The movements of the extremity were normal. Trophic lesions and color changes were not noted, and the superficial veins were not dilated. A loud humming sound with systolic accentuation was heard with

* Previously reported by Yater and White²⁰

FIG 1 *Case 1* Small arteriovenous fistula between the ulnar artery and vein. Many buckshot are present in the tissues about the elbow. A small saccular bulge in the ulnar vein at the site of the fistula is shown on the ulnar side of the forearm. Arteries are visible above and below the fistula, but of the veins only the brachial is visible.

the stethoscope in the right side of the neck and down the entire length of the right arm. It was audible even at the tips of the fingers. The greatest intensity of the murmur was in the antecubital fossa nearer the ulnar side. A thrill was palpable in the extremity, but its distribution was not as great as that of the bruit. Its point of maximum intensity was much more definite than that of the murmur, being about 5 cm below the middle of the antecubital fossa on the ulnar side. The heart rate was 80 per minute, and the rhythm was regular. The systolic blood pressure was 140 mm Hg and the diastolic 80 mm Hg in the left arm, in the right arm the systolic pressure was also 140 mm Hg, but the diastolic pressure could not be determined, the sounds being heard loudly down to the zero point. Closure of the fistula by compression over the point of maximum thrill did not alter the pulse rate appreciably, but the systolic blood pressure in the left arm dropped to 130 mm Hg. The Kahn test of the blood was 4 plus, hemoglobin, 88 per cent (Newcomer), leukocytes, 5200 per cu mm. The urinalysis was normal. Determination of the oxygen content of the blood in the superficial veins of the right arm showed that the blood was practically arterial. A roentgenogram of the chest revealed moderate enlargement of the heart.

An arteriogram was made by injecting 10 cc of Thorotrast into the brachial artery at about its middle (figure 1). Because of the high puncture point a tourniquet was used instead of a sphygmomanometer cuff to occlude the vessels above. A large number of buckshot were shown in the tissues about the region of the elbow. The brachial artery and the arteries of the forearm were well demonstrated, especially the radial and the interosseous. A moderate number of smaller arteries were shown. On the ulnar side of the forearm a short distance below the elbow joint there was a small rounded shadow representing a localized saccular dilatation of the ulnar vein at the site of the fistula. The veins below this point were not demonstrable, but the brachial vein above the elbow was quite obvious. The fistula was apparently one connecting the first part of the ulnar artery and vein. The ulnar artery itself at that point could not be clearly seen because of the presence of buckshot, nor was it possible to say positively that any of the small arteries running downward from this region was the ulnar. They appeared to be more probably muscular branches of the radial artery.

Since it was thought the cardiac enlargement was due to the fistula, operation was advised but was refused. The boy was examined again three years later. He was in excellent health, and there was no appreciable change elicited in the physical examination. Operation was again refused.

Comment Although it seemed that the increased size of the heart was due to the fistula, the fistula was undoubtedly a very small one. To begin with, the affected vessels were relatively small. There was little change in the circulatory status when the fistula was closed. The bruit and thrill of a small fistula are just as intense as those of a large one, sometimes more, so that these signs may not be used as indicators of size. The arteriographic features indicating a small fistula were (1) that the veins were not demonstrated below the sac, (2) the sac was small and localized, and (3) the arteries both above and below the fistula were well shown.

Case 2 Small fistula between the popliteal artery and vein The patient, L. D., a negro aged 44 years, was admitted to the Gallinger Municipal Hospital on July 18, 1935, complaining of chills, fever and pain in the lower right axillary region, which he claimed had begun suddenly about 24 hours before. For about a year he had had a productive cough, increasing weakness, night sweats, low grade fever, occasional

diarrhea, occipital headaches, some loss of weight, vertigo, tinnitus, palpitation of the heart and some dyspnea on exertion. He had been shot with a shotgun in the right popliteal region in 1907. He had had pneumonia, gonorrhea, a chancre and typhoid fever. He did not appear to be very ill. Physical examination was essentially negative except for evidence of pneumonitis in the lower part of the right lung, moderate enlargement of the heart with a blowing systolic apical murmur, and the following findings in the right lower extremity. The latter was larger than the left, having a circumference about 1 cm greater both above and below the knee. A marked systolic thrill was palpable whose greatest intensity was in the right popliteal fossa, but which was felt half way up the posterior surface of the thigh and half way down to the ankle. A loud, harsh bruit was heard with the stethoscope in the popliteal fossa and was transmitted up the posterior surface of the thigh to the back and abdomen and down the leg to the plantar surface of the foot and to the tips of the toes. This was practically continuous, with systolic accentuation. Both thrill and bruit ceased when the femoral artery was compressed above Scarpa's triangle. The blood pressure in the arms was 180 systolic and 100 diastolic. In the right thigh it was 248 systolic and 100 diastolic, while in the left it was 220 systolic and 120 diastolic. The temperature was 102° F, the pulse rate was 120 per minute and the respiratory rate was 26 per minute. Urinalysis was normal. The hemoglobin was 75 per cent, the erythrocytes numbered 3,760,000 and the leukocytes 18,000 per cubic millimeter of blood with 63 per cent polymorphonuclear leukocytes and 18 per cent band forms. The Kahn test of the blood was negative. A roentgenogram of the chest showed a small area of opacity in the right apex and an irregular area of increased density in the basal portion of the right lung. The temperature continued to be elevated a degree or two each afternoon, but the symptoms were soon greatly relieved by bed rest. Attention was then focused on the arteriovenous fistula of the right popliteal artery and vein.

The blood pressure gradually dropped, and on July 25 it was 134 systolic and 84 diastolic in the arms, 180 systolic and 90 diastolic in the right thigh, and 164 systolic and 90 diastolic in the left thigh. With compression over the arteriovenous fistula the blood pressure rose to 148 systolic and 100 diastolic in the arms and to 170 systolic and 110 diastolic in the left thigh. At the same time the pulse rate dropped from 95 to 88 per minute. The venous pressure rose from 86 mm to 110 mm of water. The blood volume as determined by the Congo red test was 5800 cc. The circulation time as determined by the saccharine test was 14 seconds. Blood from a vein in the right thigh was bright red.

Roentgenograms of the middle of the right lower extremity were made after the injection of 20 cc of Thorotrast into the right femoral artery in the region of Scarpa's triangle, with the artery occluded just above by the fingers of an assistant. Although the artery and not the vein was injected, as indicated by the pulsations in the syringe after piercing the vessel, and although closure of the artery above the point of injection was maintained by pressure, it was mainly the veins that were demonstrable in the films (figure 2). The femoral and popliteal veins were greatly enlarged, more especially in the knee, and just below the joint there was a saccular down-pouching of the popliteal vein. Part of the great saphenous vein was visible above the knee. The popliteal vein just below the fistula was seen and also some of its small muscular tributaries, but all were of small size and not tortuous. In the upper part of the film a few small arteries were also noted (not shown in the photograph). Some scattered buckshot were present in the tissues. On another day the injection was repeated (figure 3). The first roentgen-ray exposure was made a trifle later than on the former occasion. The appearance was essentially the same, except that the femoral vein was not visible, but the great saphenous vein, which anastomoses freely with the popliteal vein, was well shown.

On August 13 an operation was performed to remove the segment of the popliteal artery and vein including the fistula. It had been assumed that the collateral circulation was well developed because of the great age of the fistula. But in spite of all postoperative precautions gangrene of the stump followed, and the right leg was

FIG 2 Case 2 Small arteriovenous fistula between the popliteal artery and vein. No arteries are visible. The femoral vein is distended, the popliteal vein is greatly distended and presents a rounded saccular bulge below the knee. The part of the popliteal vein below the fistula is small. Part of the great saphenous vein is shown near the femoral vein. Buckshot are present in the tissues.

amputated above the knee on August 25. However, infection developed in the stump, followed by septicemia, and death occurred on September 21.

Examination of the segment of the popliteal artery and vein containing the fistula showed that both vessels were moderately enlarged and thickened. The fistula was small, admitting only a small probe. The venous sac which had been demonstrated in the roentgenograms was not evident in the empty vessels. Apparently it was not an anatomical sac but merely a dynamic or functional one which existed only during life.

The pulmonary condition for which the patient was hospitalized did not progress during the period of hospitalization. Actually, the pneumonitis of the right lower lobe resolved, as indicated by physical examination and roentgenograms of the chest. The patient's cough subsided but returned a few days before death. Several ex-

FIG 3 Case 2. Another film after a second injection of Thorotrast. The contrast medium has left the femoral vein and fills mainly the great saphenous vein and the popliteal vein.

aminations of the sputum failed to reveal tubercle bacilli. Permission for necropsy could not be obtained because the patient had no known relatives.

Comment Although the arteriograms in this case were not essential to the diagnosis of arteriovenous fistula nor to the determination of the location of the fistula, and although mistakes in judgment were made, interesting information was obtained from the experience afforded by the case. As Allen and Camp¹³ have stated, arteriography is valuable in increasing

our knowledge of the mechanics of vascular diseases. In the case here reported it is seen that the force of arterial blood passing into a vein through a small opening may produce during life a localized dilatation in the vein which roentgenographically resembles an aneurysmal sac but which is not a true aneurysm. The small size of the fistula was demonstrated arteriographically by the absence of dilated and tortuous veins distal to it. The absence of arterial shadows shows how rapidly blood flows from the artery into the vein even through a small fistula, but in the case of a small fistula apparently most of the blood entering the vein through the fistula returns immediately toward the body and relatively little goes into the veins of the limb distally.

The great age of the fistula without evidence of chronic passive congestion in this case was an indication of its small size. The cardiac hypertrophy was due probably more to hypertension than to the fistula. A small fistula is not necessarily conducive to the development of an adequate collateral circulation, even after many years of existence. In fact, it is impossible on the basis of arteriographic studies to determine whether a fistula of any size stimulates the formation of a very adequate collateral arterial circulation, although in all other vascular diseases of the extremities the extent of the collateral circulation is one of the most important uses of arteriography. However, Reid,²¹ on the basis of clinical and experimental studies, concluded that an arteriovenous fistula is the most powerful stimulus there is to the development of collateral circulation of the surrounding vessels. Nevertheless, it is safer to assume in any case of arteriovenous fistula that the collateral circulation is not adequate, and measures to assure an adequate collateral circulation should be instituted before operation. Such measures consist mainly in the daily occlusion of the artery leading to the fistula for a few weeks prior to operation. Increasing periods of occlusion from five to fifteen minutes one to several times a day should be instituted. Had this procedure been followed in this case the patient's limb and life might have been saved, although it is well known that ligation of the popliteal artery is fraught with more danger than that of the femoral artery higher up.

Case 3. Small fistula between the femoral artery and vein. A white man, G. B., aged 34 years, entered Georgetown University Hospital on January 7, 1936, complaining of weakness, dyspnea on exertion, pallor, nocturia, and swelling of the ankles. The illness had apparently begun about 10 months before with intermittent pains in the right side of the body from the shoulder to the hip, present mainly on exertion. After several months these had ceased. Much later the other symptoms had become noticeable. The past history was unimportant except for a shotgun wound in the left thigh when the patient was eight years old. About three weeks later he had noticed a palpable thrill just distal to the left inguinal ligament. About seven years later arteriovenous aneurysm was diagnosed on the occasion of a fracture of the left hip. On admission he was found to be poorly nourished, pale and weak. The heart was slightly enlarged, and there was a loud systolic apical and precordial murmur. The blood pressure was 132 systolic and 56 diastolic. Numerous small scars were

present in the skin of the upper, anterior part of the left thigh. There were visible strong pulsations of the femoral artery in Scarpa's triangle with slight bulging in that region. A strong thrill was palpable in the same area. A loud systolic murmur was audible from the umbilicus to the tips of the toes, with greatest intensity over the femoral artery just below the inguinal ligament. There were no trophic changes, and there was very little difference in the measurement of the lower extremities. With pressure over the apparent site of the fistula the pulse rate instantly dropped from 98 to 90 per minute, the venous pressure rose from 72 to 174 mm. of water, and the blood pressure fell 10 mm. Hg. The blood pressure in the left leg was 140 systolic and 68 diastolic and in the right leg 124 systolic and 64 diastolic. The urinalysis showed some albumin and a few casts. The hemoglobin was 28 per cent (Newcomer), the erythrocytes numbered 1,980,000 and the leukocytes 6,800 per cubic millimeter of blood, with 68 per cent polymorphonuclear neutrophils. The blood non-protein nitrogen was 45 mg. per 100 c.c. of blood. The phenolsulphonephthalein test of renal function showed 12 per cent elimination of the dye during the first hour and 18 per cent during the second hour. The Kahn test of the blood was four plus. The temperature was elevated irregularly daily to 101.5 to 103° F. with occasional morning remissions to normal. The pulse rate varied from 100 to 130 per minute.

An arteriogram was made with some difficulty, since the fistula was apparently so high in the thigh that the femoral artery had to be injected close to the inguinal ligament and therefore close to the point where the assistant occluded it. Furthermore, firm compression at this point was quite painful. However, a fair arteriogram was obtained (figure 4). Shadows of many buckshot were seen in the tissues of the upper thigh. There were no arteries definitely visible. A large, somewhat oval and mottled shadow of the dilated upper part of the femoral vein was visible. Below this on the medial side of the femur were the main vein and a moderate number of small veins, not very tortuous. On the lateral side of the femur other straight veins were evident.

Subacute bacterial endocarditis was considered a probable diagnosis in spite of persistently negative blood cultures, but on reflection it was deemed possible that the vegetations might be present in the arteriovenous fistula and not in the heart, as in the case of Hamman and Rienhoff²². Accordingly, it was decided to attempt extirpation of the fistula, but only after a period of daily occlusions of the femoral artery to stimulate the development of collateral circulation, even though the fistula was considered to be small and had existed 26 years without evidence of heart failure or trophic changes. During this preparatory period evidence of increasing renal insufficiency developed, the blood non-protein nitrogen rising to 70 mg. per 100 c.c. of blood.

On January 29 operation was performed by Dr. Fred Sanderson. The fistula was found to be located about 2 cm. below the origin of the profunda femoris artery, which like the common femoral artery was very large. The femoral vein was greatly dilated in this region. There were many vessels in the vicinity, mainly veins, and the operation was difficult. The segments of the femoral artery and vein containing the fistula were extirpated. In order to control hemorrhage it was unfortunately necessary to ligate the great saphenous vein, and a hemostat had to be left on a tributary vein. Examination of the specimen removed showed a fistula about 2 mm. in diameter connecting the artery and vein directly and containing no vegetations.

After the operation the arteries of the leg and foot were still felt to pulsate, and the extremity remained almost as warm as the other. However, the limb swelled a great deal and became somewhat livid because of venous obstruction. The day following the operation a diastolic murmur became audible over the base of the heart for the first time. A day later petechiae first appeared. Hiccough began and persisted. The operative wound became infected. Ten days after the operation profuse venous hemorrhage occurred from the wound, and a few hours later the patient died.

FIG 4 Case 3 Small arteriovenous fistula between the femoral artery and vein. No arteries are visible. The upper part of the femoral vein is greatly dilated. Below this fusiform venous aneurysm the veins are visible but are not tortuous. Many buckshot are present in the tissues.

Necropsy revealed bacterial vegetations on the aortic valve but no evidence of chronic endocarditis. The femoral vein was completely thrombosed. There was ulceration of the profunda femoris artery, and a small communication with the vein had resulted from this lesion.

Comment The fistula was small and had existed for years, but some part of the arterial blood to the affected extremity apparently passed into the veins through the fistula, although a goodly part also went down the profunda femoris artery. The direct course of the veins instead of a tortuous one indicated that the fistula was small. If it had not been necessary for controlling hemorrhage to tie the great saphenous vein the fistulectomy would undoubtedly have been successful, since the fistula was just distal to the origin of the profunda femoris artery. However, the venous return was obstructed and thrombosis occurred in the veins, resulting in severe venous stasis in the limb. The foot remained warm and the arterial pulsations were present.

*Case 4 Large fistula between the popliteal artery and vein** The patient, G K, a negro aged 52 years, had been shot in the region of the left knee with a 0.38 caliber rifle in 1921, 14 years before. The bullet entered the skin just below the patella on the anterolateral aspect of the leg and came out in the lower popliteal region. In three or four days the leg became greatly swollen from the knee down. It had remained almost as large from that time but was always less swollen after a period of bed rest. An ulcer had appeared about a year later on the middle of the anterior aspect of the leg. This had become quite large but some healing had occurred from time to time. The toe nails of the left foot had become thickened and had not grown as fast as those of the right foot. For the previous five years there had been intermittent bleeding from the rectum of variable amounts of bright blood. Some dyspnea on exertion had been noticed latterly.

The essential points of the physical examination were as follows. The heart was moderately enlarged, the visible apex impulse being 10.5 cm from the mid-sternal line (the clavicle measured 18 cm). There was a systolic precordial murmur. A strong pulsation synchronous with the heart beat was palpable in the left lower quadrant of the abdomen. The left leg was considerably larger than the right below the knee. The measurements were as follows:

Circumference, middle of thigh, right—43 cm, left—41.8 cm

Circumference of calf, right—31 cm, left—37.3 cm

Distance from anterior superior iliac spine to internal malleolus, right—97.5 cm, left—100 cm

A large area on the anterior and lateral surfaces of the left leg was deeply pigmented, and there was a small, irregular granulating ulcer in its middle (figure 5). The left ankle was limited greatly in its movement. The left foot was red, very moist and quite warm. The superficial veins were prominent over the left thigh and upper calf, and the great saphenous vein was very large (about 2 cm in diameter) from just below the knee up nearly to Scarpa's triangle (figure 6). Blood drawn from this vein was as red as arterial blood. The femoral artery was seen to pulsate extremely in the upper part of the thigh, and could be occluded with the fingers with difficulty. The popliteal artery also pulsated greatly. A strong thrill was palpable in the popliteal fossa and radiated upward and downward for several inches. A very loud, almost continuous bruit with systolic accentuation was audible with greatest

* Case of Dr. Paul Putzki at Providence Hospital.

intensity in the popliteal fossa, but could easily be heard down to the tips of the toes and up to the umbilicus

The pulse rate was 92 per minute, and on occlusion of the popliteal artery by compression it dropped immediately to 64 per minute. The blood pressure in both arms was 130 systolic and 60 diastolic with the fistula open and 150 systolic and 80

FIG 5 Case 4 Large arteriovenous fistula between the popliteal artery and vein
Affected leg enlarged, pigmented and ulcerated

diastolic with it closed. The blood pressure in the left thigh was $300 +$ systolic and 60 diastolic. In the right thigh it was 190 systolic and 120 diastolic with the fistula open and 220 systolic and 130 diastolic with it closed. The venous pressure in the right antecubital vein was 68 mm of water with the fistula open and the same with it closed. In the right saphenous vein it was 84 mm, in the left it was 160 mm, and

the column oscillated with the heart beat. The circulation rate with the saccharin test was 31 seconds when the fistula was open and 23 seconds when it was closed. Thermographic studies showed an increase of temperature of the skin in the left popliteal space, but very little change elsewhere in the affected limb.

Studies of the rectum did not reveal any intrinsic lesion, and it was thought that

FIG 6 Case 4 Great saphenous vein greatly dilated

the pulsations in the left lower quadrant of the abdomen were due to dynamic pulsation of the iliac artery on that side and that the bleeding was due to venous engorgement about the rectum.

Two series of arteriograms were made on different days. The first time 25 c c of Thorotrast were used, but due to the large size of the venous bed in the extremity the shadows were not as dense as usual. The second time better detail was shown by the injection of 50 c c. Several films were taken in succession as rapidly as pos-

sible, one beat being allowed to go down the limb between films (figures 7 to 10). The only arteries visible were some small ones high up in the thigh. In the first film the popliteal vein was seen to be greatly distended and some of its tributaries filled, the great saphenous vein with one of its branches was visible (figure 7). In the second film the popliteal vein appeared to be even larger and more of its tributaries

FIG 7 Case 4 Large arteriovenous popliteal fistula. Film number 1 of a series. The popliteal vein is greatly dilated and forms a pouch below the knee. The great saphenous vein is visible. Tributary veins are very tortuous.

in the leg were visible, resembling large round worms, there was also a long, coiled vein in the thigh, but the saphenous vein was no longer evident. The third film was essentially the same, but the veins in the calf were more prominent (figure 8). In the fourth film there was just a dim shadow of the popliteal vein, but the veins in the calf were very numerous, and more small veins were visible in the thigh (figure 9). The fifth film showed the small veins very indistinctly, but the femoral and saphenous

FIG 8 Case 4 Film number 3 The great saphenous vein is no longer visible. Many coiled veins are visible below the knee.

veins were visible, although they were not as dense as originally (figure 10) The sixth film was quite similar The roentgenograms also showed enlargement and evidence of osteitis of the tibia and fibula

The patient was kept in the hospital several weeks and daily occlusion of the femoral artery performed The leg became smaller and the ulcer healed Before operation was contemplated the patient secretly left the hospital

Fig 9 Case 4 Film number 4 The veins in the thigh are barely visible Those in the leg are still readily apparent

Comment This was a case of a large fistula which had existed 14 years without congestive heart failure. Trophic changes were prominent. Practically all of the blood below the knee went through the veins, which ap-

FIG 10 Case 4 Film number 5 The popliteal and great saphenous veins are again evident. The veins below the knee are barely visible.

parently assumed the function of arteries in nourishing the tissues. This function was insufficient because of difficulty in the return of deoxygenated blood from the limb. The arteriograms indicated that the deoxygenated blood left the leg slowly by the same veins through which it entered. Ap-

parently there were two simultaneous, opposite currents in the veins below the fistula

CONCLUSIONS

The following points may be determined by arteriography in cases of arteriovenous fistula (1) the site of the fistula, (2) the size of the fistula, and (3) perhaps the mechanism of the circulation in the limb below the fistula

The site is indicated by the point of greatest bulge in the affected vein, which frequently just below the fistula forms a rounded saccular pouch

The size of the fistula is shown by the degree of visibility of the arteries in the films, by the size of the large veins, and by the number and tortuosity of the smaller veins, particularly those distal to the fistula. In cases of small fistula the arteries may be visible and there are no or relatively few veins visible below the fistula. The few small veins that may be visible are not tortuous. Even in the case of a small fistula between larger vessels the arteries may not appear in the films. In cases of large fistula the arteries are probably never visible, but the large veins are prominent, and the small veins, especially those distal to the fistula, are enlarged, seemingly increased in number and very tortuous.

When the fistula is large the veins distal to the fistula must assume the function of arteries. The return of deoxygenated blood from the limb below the fistula apparently occurs through the same veins down which the arterial blood passes.

The extent of the collateral circulation in cases of fistula is very difficult to judge from arteriograms, since with larger fistulae the arteries are not visible. It is safest to assume in every case of arteriovenous fistula that the collateral circulation is not sufficient and to institute measures to assure an adequate collateral circulation before the operation is performed. In arterial diseases of the extremities, on the contrary, the extent of the collateral circulation can be rather accurately determined by the aid of arteriography.

EFFECTS OF GASTRIC AND INTESTINAL HYPERPERISTALSIS ON THE ELECTROCARDIOGRAM AS DEMONSTRATED BY SIMULTANEOUS MECHANOGRAMS AND INDIRECT AND SEMIDIRECT ELECTRIC LEADS *

By I HARRISON TUMPEER, S M , M D , *Chicago, Illinois*

REGISTRATION of gastric and intestinal hyperperistalsis on the electrocardiogram has been reported in a previous study ¹ The sources were the gastric activity in a baby with congenital hypertrophic pyloric stenosis and the intestinal contractions in a child with congenital hypertrophic dilatation of the colon (Hirschsprung's disease), and in an elderly adult in whom borborygmi occurred in the course of a routine electrocardiogram Hyperperistalsis was visible in the first two conditions and audible in the last

The peristaltic effect upon the electrocardiogram is not even considered in such a review as Esler and White's ² nor is it mentioned in Mortensen's ³ study of abnormal electrocardiograms The influence of such smooth muscle activity seems entirely ignored although suggestive effects are present in some of Wenckebach and Winterberg's ⁴ observations on the effect of vagus pressure and in a group of routine tracings from the Heart Station of Michael Reese Hospital examined by the author Alvarez and his co-workers ^{5, 6, 7} have reported electrical registration of peristalsis in man and animals In the latter simultaneous mechanograms were submitted Richter ⁸ has demonstrated electrogastrograms of the exposed stomach in etherized dogs, and more recently Hasama ⁹ studied the pendulum peristalsis in the small intestines by direct electrodes Puestow ¹⁰ worked with isolated intestinal loops and muscle strips obtaining electrical and mechanical records Berkson ¹¹ as well as Puestow demonstrated that these effects maintain their relationship even after the tissue has been isolated from the central nervous system, indicating an intrinsic mechanism controlling peristalsis Nevertheless, no previous observations on simultaneous electrical and mechanical phenomena have been demonstrated in the intact human subject The present study was undertaken to record objectively the simultaneous mechanical and electrical registrations during gastric and intestinal hyperperistalsis

THE PRESENT STUDY

Gastric hyperperistalsis was studied in an adult male with pyloric obstruction and marked visible peristalsis

* Received for publication February 6, 1936

From the Sarah Morris Hospital for Children and the Heart Station, Michael Reese Hospital, Chicago

With the technical assistance of Bessie Phillips, Electrocardiographic Technician, Heart Station, Michael Reese Hospital, Chicago

CASE REPORT

E R, male, 42 years old, was admitted to the Michael Reese Hospital, medical service of Dr Wm C Buchbinder, September 21, 1934, with the admission diagnosis of pyloric obstruction due to duodenal ulcer, and signed his own release because he refused surgical treatment, October 5, 1934. His symptoms had begun two years before with postprandial, peri-umbilical pain occurring one or two hours after meals, associated with a sensation of weakness and nausea, and more recently with vomiting at the onset of the pain. He had vomited food eaten one or two days previously. Vomiting had increased in frequency so that recently he dared not eat a meal but nibbled small amounts of food continuously. Earlier in the course of the illness the Sippy regime had been prescribed at another institution but appeared to aggravate the symptoms. One year ago baking soda had given slight relief, but in the past few months it had increased his distress by the resulting gas formation. The pain has sometimes been relieved by cold milk, and always by vomiting. He awakened three to five times nightly. He had lost seven pounds in the preceding six months and three in the preceding two weeks. For the past two months he had felt weaker, and recently had vomited practically everything, he had been continuously hungry but could not eat. There had been no bowel movement for three days before admission.

Physical examination revealed a poorly nourished, white male, not acutely ill. The chief finding was marked epigastric peristalsis with gurgling and splashing sounds when the upper abdomen was tapped. As much as 2000 cc of gray brown liquid were aspirated in a series of frequent gavages. The blood picture, blood sugar, non-protein nitrogen and urine were within normal limits. Blood pressure was 108 to 112 systolic and 84 to 72 diastolic.

Fluoroscopic Report "Stomach contains a considerable amount of residual fluid. The fundus is dilated, and the walls reveal marked peristalsis. Definite antral and pyloric spasm is present. Tenderness is elicited over the pylorus. There is 80 per cent retention in five hours. The duodenal cap does not fill immediately, and is markedly defective when filled in one-half hour."

Roentgenographic report "The film confirms the fluoroscopic findings, revealing a pyloric obstruction and a defective cap. Whether the cause of obstruction is duodenal or pre-pyloric is not revealed owing to the pronounced pylorospasm."

Study A Lead III was taken on the patient with a slowed camera. The mechanical registration was accomplished by air pressure effects on a Frank capsule¹² to whose rubber diaphragm a tiny mirror was fastened throwing a beam of light on the slit in the camera of the electrocardiograph so that both electrical effects by means of Lead III and mechanical effects could be registered on the film simultaneously. In this part of the study the patient swallowed the usual stomach balloon which was attached by rubber tubing to the Frank mirror-holding capsule. (Figure 1)

Comment The undulation in the base line of the electrocardiogram occurs with the passing of the peristaltic wave usually beyond the mid line. It is not an artefact and resembles the kymographic record of a peristaltic wave. This has been pointed out by Alvarez and myself. The excursions differ from the kymographic record because the rapidity of the film distorts the picture by widening and flattening the curves. The black band tracing is the result of changes in the pressure of the stomach balloon and represents only crudely, as will be explained, the mechanogram of the stomach. The

superimposed low excursions in the latter occurring about every three to four seconds demonstrate nicely the respiratory effect

If the longer excursions are examined it will be noted that a slow rise of the balloon record usually accompanies the undulation in the electrocardiographic base line. This, then, is the first reproduction of simultaneous electrogastragrams and mechanogastragrams. However, there can be no

FIG 1 Simultaneous electrogram by Lead III and mechanogram by stomach balloon. Note shift in base line of electrocardiogram accompanying balloon tracing. Note also minor respiratory and cyclic cardiac fluctuations.

identical parallelism because the electrocardiographic excursion by this method does not begin until the visible peristaltic wave has crossed the fundic portion and traverses the mid line, a fact previously noted. In other words, the peristaltic wave can be seen moving across the left hypochondrium to the right even without photographic confirmation, but the actual deflection in the electrocardiographic base line does not appear until the mid line has been crossed, probably because of the nature of the summation of the stresses. Furthermore, absolute parallelism of electro- and mechanograms by the balloon method is only exceptionally achieved because the mechanical method has a lag and for other reasons gives only a crude reproduction of stomach activity. First, the balloon is never large enough or in sufficient contact with the stomach wall to mirror the entire organ. Second, at a given moment, the balloon may lie in the pyloric portion and fail to reproduce fundic waves, particularly if the algebraic sum of contraction wave preceded by dilatation fails to alter intragastric and therefore balloon pressure. Third, even if the balloon lies in the path of the wave the algebraic sum of all effects on pressure may be zero. Fourth, pyloric waves are more effective than fundic ones. Fifth, the ordinary stomach balloon usually lies in the fundic portion. To obtain a more comprehensive picture of the entire stomach in action which usually has two or more waves passing at the same time, two or three separate balloons could be used lying in different portions of the stomach. However, even this method is not entirely accurate. The electrical stresses summate in a manner different from the mechanical changes. It is obvious that under certain circumstances, the electrical stresses may nullify each other in the direction of the lead in use and result in no change or shift in the electrical record. Nevertheless, enough is shown

to give objective evidence of mechanical muscular activity associated with electrical changes

Study B Direct leads were placed on the abdomen to approximate the positions of pyloric and cardiac ends of the stomach. The stomach balloon was connected to the Frank capsule as in the preceding record (Figure 2)

FIG 2 Simultaneous gastric electrogram by direct abdominal leads and mechanogram by balloon. Note marked excursions of electrical and mechanical tracing and lack of absolute parallelism

Comment By this method the electrical undulations were extremely marked. Polarity was such that the electrical and mechanical records sometimes moved in opposite directions as the contractions enhanced the mechanogram deviations. The record submitted minimizes the electrical excursions because the string repeatedly moved off the camera slot and had to be returned. At one point the measurement indicated a 30 millivolt change. To answer the question whether the marked excursions might be artefacts due to the position of the abdominal wall and the change in position of the electrodes which were forced up during the marked peristaltic bulgings, the patient was instructed to vigorously distend and contract his abdomen by deep respirations. These measures and deep palpation of the epigastrium produced no significant effect. Therefore, it seems that gastric peristalsis alone produces a marked electrical wave which can be picked up when direct abdominal leads are employed. Furthermore, it was noted that the closer the left lead, i.e., the cardiac, was placed to the right, i.e., the pyloric, the greater the electrical excursions.

Study C The typical Lead III was restored, but the mechanical deviation was recorded by fastening a tambour commonly employed to record the cardiac apex beat in the path of the peristaltic wave (a) left upper quadrant in the fundic region, (b) mid line and (c) in the region of the pylorus

Comment Although the observations correspond with those obtained by the preceding methods, namely, that electrical and mechanical deviations were demonstrated together, there was more difficulty because the nature of the peristaltic wave prevented accurate apposition of the tambour to the abdominal wall at all times

Intestinal hyperperistalsis was observed in a girl with congenital hypertrophic dilatation of the colon (Hirschsprung's disease)

CASE REPORT

R M., a female of six and one-half years, was admitted to the Sarah Morris Hospital, service of Dr Jesse R Gerstley, October 18, 1934, for an acute dysentery which had affected three other members of the family after a meal of canned meat, and was discharged recovered from dysentery, November 5, 1934. Interest in connection with the present study lay in the fact that constipation had been present since the child was 14 days old. At this time she had no bowel movement for five days. At present she requires an enema every two or three days without which there is no evacuation. There has been loss of sphincter control at intervals since infancy. These involuntary movements are sometimes loose and associated with simultaneous urination. Further, there is frequent involuntary urination when the bowels are unusually constipated. (It should be stated here that atony of the bladder is commonly associated with atony of the colon and is usually overlooked in the history and examination.) It was also volunteered that the child had never been quite well and that her extremities had remained poorly developed while her abdomen became large and protuberant.

Physical examination revealed a small undernourished girl with thin arms and legs and an unusually large abdomen, slightly toxic and feverish. Aside from the specific illness for which she was admitted, it was noted that a relatively long torso gave a peculiar appearance. There were large peristaltic waves passing from right to left across the abdomen and also down the left side of the abdomen from above, following the course of the colon. Tympanites was present, and the bladder was distended. An opaque enema revealed a localized segment of dilated distal colon. The enema filled the dilated loop and extended backward to fill a tremendously dilated colon throughout. After 24 hours practically the entire enema was still present within the colon.

Study D Lead III which was used in other portions of this report was employed for the electrical record. A tambour was placed on the abdomen connected for photographic registration of mechanical effects as described above. (Figure 3)

Comment The wide deviations of the band which again reproduces the mechanical record indicates the violence of the intestinal peristalsis. This is further evidenced by the tracing leaving the limits of the camera in several places. Equally conspicuous is the marked rise and fall in the electrocardiographic base line associated with the greatest activity of peri-

stalsis In the portion of the record here illustrated it is mere chance that the electrical and mechanical excursions are in the same direction because a wave in another segment of colon may be associated with an electrical wave in the opposite direction depending on the interference and direction of the interference of the electrical axis A review of results in a previous study

FIG 3 Simultaneous electrogram by Lead III and intestinal mechanogram by tambour
Note degree and direction of fluctuations

in intestinal hyperperistalsis in a two year old child with Hirschsprung's disease and in a 60 year old man with borborygmi will recall that there is no regularity in curves because the intestinal wave is a variable at any given moment in direction, intensity and location These variable factors must affect the electrocardiogram irregularly The waves in the present subject were of marked intensity, and the algebraic sum of the peristaltic effects, checked visually, is illustrated in the reproduction It is obvious that the tambour method is limited by the fact that it can only reproduce the mechanical changes of one small area, but it is useful in objectively denoting the mechanical effect of peristalsis and is an objective substitute for mere visual evidence

SUMMARY

1 Simultaneous mechanical and electrical registration of gastric hyperperistalsis is recorded for the first time in the intact human subject upon the electrocardiographic film

a The electrogastrogram and the mechanogastrogram resemble each other in form and contour because there is fixed polarity in gastric peristalsis

b The exact reflection of the electrical action current in gastric peristalsis cannot be mirrored by the balloon or tambour method because of the limitations of this method of reproducing the mechanical factor in contraction

i The algebraic total of contraction in electrical terms in its effect on the electrocardiogram is recorded

ii The algebraic total of stomach activity by changes in intragastric pressure or pressure within balloon or tambour is at best but crudely reproduced

2 Simultaneous electrical and mechanical registration of intestinal hyperperistalsis is recorded

3 This study accomplishes its purpose which was to confirm the author's previous observations by submitting objective evidence of simultaneous gastric and intestinal hyperperistalsis accompanying disturbances of the electrocardiogram coincident with visible peristalsis

4 An exact picture may be possible by simultaneous cinematographic roentgenographic reproduction of visible peristalsis using a double coated barium treated balloon and electrocardiographic records run on film at equal speeds

5 This study confirms the fact previously established that the movements of the base line of the electrocardiogram are the electrical evidence of hyperperistalsis and can properly be called hyperperistalt-electrograms

6 Indirect electrical leads are adequate and may serve a useful function in the study of peristalsis

I wish to acknowledge indebtedness to Dr Heinrich Necheles of the Department of Gastro-Intestinal Physiology for his suggestions and assistance and to Dr Louis N Katz, Director of Cardio-Vascular Research, for advice on methods of registration and for his valuable suggestions in the preparation of this report

THE VALUE OF THE SEDIMENTATION TEST AS A DIAGNOSTIC AID *

By JOSEPH E. HIRSH, M D , F A C P , *Birmingham, Alabama*

IN 1918, Fåhræus¹ called attention to the fact that there was an increase in the sedimentation rate of red blood cells in the citrated blood of pregnant women. This was immediately hailed as a new test for pregnancy. However, it was soon discarded, as it was found to be unreliable, until after the third month of pregnancy.

Fåhræus was not the first to make this interesting observation. Galen, as early as the year 200, pointed out that if blood were allowed to stand in a tube, a white line would form at the top of the blood. While he did not recognize this white line as coagulated plasma, he did regard it as pathological, and referred to the phenomenon as the "Crusta Phlogistica." In 1791, John Hunter noted that the erythrocytes of the blood settled more rapidly in inflammatory conditions than they did in normal blood. Further observations were made by Nasse in 1836, Davy in 1839, Muller in 1844, and Biernacki in 1894.²

The test was then forgotten until the work of Fåhræus. In 1920, Linzenmeier³ called attention to its usefulness in the diagnosis of pyosalpinx. Friedlander in 1924, Polak in 1926, and Baer and Reis, in the same year, called further attention to its use in gynecology and obstetrics, while Wehrbein, in 1928, stressed its importance in urology.

TECHNIC

Unfortunately, there are three different methods of performing this test, and each in turn has different modifications, made by various investigators. The first method is that of Fåhræus and Westergren. The underlying principle in this consists of measuring the distance through which the red blood cells fall in one hour, and the results are recorded in millimeters. The second is the Linzenmeier³ method, in which a record is made of the time in minutes necessary for cells to settle a given distance of 18 millimeters in a column of blood 50 millimeters high. The third is the graphic method of Cutler,⁴ in which the use of a graph is especially valuable, as it shows any sudden change in velocity.

Greisheimer⁵ and his associates have pointed out that the average sedimentation rate in one hour for "normal" subjects appears to be reasonably concordant for the three methods, despite the wide difference in the width of the tubes, the length of the fluid column, and the anti-coagulant concentration.

Wintrobe and Landsberg⁶ have emphasized the necessity of a standard test and pointed out many possible sources of error in performing the test.

* Received for publication February 6, 1936

The most important are the following: The effect of the anti-coagulant, the influence of the bore and length of the tube, the influence of the inclination of the tube, the effect of the room temperature, the changes in the suspension stability of blood, as influenced by delay, in carrying out the test.

In our work, the Schiller modification of the Fåhræus-Westergren method was used. It has several advantages, the most important being that the technic is simple, the time required for observation is only one hour, the recording of only one reading is necessary, and the blood is obtained from the finger and not the vein.

A capillary tube 138 millimeters long and 1 millimeter in calibre is used. There are two marks on the tube, the first being 13 millimeters, and the second 63 millimeters from the tip. After preparing the patient's finger in the usual manner, and making a quick puncture, a 5 per cent solution of sodium citrate is drawn up to the first mark, and the patient's blood is immediately drawn to the second mark, great care being exercised to prevent the formation of air bubbles. The tube, which contains 0.4 c.c. of citrate and 1.6 c.c. of blood, is gently tilted 20 times to allow the solutions to mix. The tip of the tube is then plugged with a tiny piece of soap and carefully placed vertically in an especially constructed rack, which has clamps to hold the tube very firmly. After exactly one hour, the amount of clear fluid at the top of the tube is read and recorded in millimeters. The normal rate for males is 2 to 8 millimeters, the average being 4 millimeters, while the normal for females is 3 to 10 millimeters, with an average rate of 6 millimeters. The normal rates for infants, children and senile individuals, is slightly greater, while the same is true of menstruating women.

THEORY

Various factors influence the speed with which erythrocytes settle but, as yet, the exact mechanism of the sedimentation test is not known. Numerous explanations have been advanced. Fåhræus¹ believes that increased sedimentation is produced by an alteration in the electrical charge of the blood corpuscles, causing a loss of their repelling force, and thereby bringing about their agglutination and more rapid sedimentation. Reynier⁷ holds that a difference in surface tension of blood plasma is responsible for the phenomenon. Hunt⁸ states that whatever is responsible for the increased sedimentation is contained in the blood plasma, and that it is most likely an increase in the fibrinogen. According to Snappier,⁹ the two chief factors influencing the rate of the fall are the concentration of fibrinogen and serum globulin, with hydration or degree of anemia acting as subsidiary factors. Hoverson and Petersen¹⁰ regard the variations in the individual rates as dependent largely on environmental and meteorologic conditions. According to Gram,¹¹ the sedimentation rate depends on (a) the cell volume percentage, (b) the fibrin percentage in the plasma, and (c) the temperature. On the other hand, Bortree¹² states that the relative speed of sedimentation

of erythrocytes is dependent upon the colloidal chemistry of the blood and chiefly upon the fibrinogen-globulin ratio Koelsche¹³ thinks the rate of sedimentation is directly proportional to the content of fibrin in the plasma. He points out that the blood of an anemic patient has a rapid sedimentation rate, notwithstanding its normal content of fibrin. An increase in viscosity of the blood inhibits sedimentation. Rubin and Smith¹⁴ conclude that, in general, the lower the hemoglobin content of the blood, the more frequently is increased sedimentation obtained. They believe that the volume of red blood cells exerts an important influence on the sedimentation rate, under all conditions, and that possibly physiologic changes in sedimentation are also influenced, to a great extent, by the erythrocyte factor. Thus, the lower cell volume percentage found in women would explain the greater sedimentation reactions that they give in comparison to men. Among the various explanations of the varying rate of sedimentation of erythrocytes, Banyai and Anderson¹⁵ feel that the most plausible are (a) an increase in the fibrinogen content of the blood plasma and (b) changes in the number and size of the erythrocytes. Toxin production involves a breaking down of tissue proteins, and subsequently, the products of disintegrated tissue proteins will stimulate fibrinogen formation. As Cutler¹⁶ points out, there is constantly a process of tissue destruction, accompanied by a similar amount of tissue repair. Should the amount of tissue destruction pass beyond the normal, then the stability of the blood is seriously disturbed and the red blood cells settle out quickly from the plasma, the rapidity of the settling of the red blood cells being in direct proportion to the severity of the disease.

We believe the sedimentation rate depends on the presence of a foreign protein in the circulation. In pregnancy, this is the protein of fetal catabolism, in infection, it is the protein of bacteria, and in malignancy or coronary occlusion, it is the protein of necrotic tissue.

USES

As stated above, this test was first devised as a test for pregnancy. However, more recently, it has received recognition as a useful diagnostic adjunct in other branches of medicine. Westergren¹⁷ claims that it not only has diagnostic value, but also furnishes information as to prognosis, as well as indications for therapy.

Cutler¹⁸ presents the amazing statistics of 5,000 patients, on whom sedimentation tests were made. Of this entire group, there were only five patients on whom a normal rate was obtained, in the presence of active disease. Yates and Davidow¹⁹ made 6,000 determinations on 1,700 patients and found the accuracy of the sedimentation test to be 91.4 per cent.

In our own work, we performed 488 sedimentation tests on 395 patients. Of 283 determinations that should have given normal sedimentation rates, only 11 had rates that were over the normal limit. Of the remaining 205 determinations which were expected to be abnormally high, there was not one single case that gave a rate of less than 15 millimeters.

Gallagher²⁰ presented figures on 685 normal school boys and concluded that the test produced most valuable results. In his group there were many patients with mumps and the "common cold." These gave normal rates, showing how little the sedimentation rate is affected by minor infections, of short duration.

The sedimentation test has been used very extensively in the field of gynecology. Grodinsky² called attention to an increased rate in pyelitis, pyelonephritis, pyonephrosis and perinephric abscess. He found that ureteral colic, and other urological conditions, without associated infection, gave a normal rate, and emphasized the importance of this in the differential diagnosis of pain in the lower right quadrant. He further noted that acute appendicitis without rupture had a relatively low rate, while subacute and chronic appendicitis gave even a lower figure. Polak and Tollefson²¹ cite 1,660 readings on 650 gynecological patients. They concluded that rapid sedimentation indicated infection, when the readings in pregnancy and the puerperium had been excluded. In the presence of a high rate, these authors never operate on a patient, unless there be inflammatory process too active to permit conservative procedure. Furthermore, the test is used as an indicator by these investigators, as to the proper time to discharge the patient from the hospital. The individual is not released, until the rate returns to normal, excluding, of course, all other sources of infection. Polak and Tollefson use as their dictum, "The sedimentation test never lies." Ward²² used the test in 1,140 cases and reached the same conclusion. Friedlander,²³ after testing 1,500 patients, felt that the test was extremely valuable in determining the "safe period" for operation. Schattenberg²⁴ after 1,100 tests, Rubin,²⁵ Nicholson,²⁶ and Stimson²⁷ are all in accord in this respect.

Smith, Harper and Watson²⁸ in their report of 19 cases of acute salpingitis and 38 cases of acute appendicitis, came to the conclusion that the sedimentation test is of some value as a differential point between these two conditions. Nicholson²⁶ was of the same opinion.

Mathieu, Trotman and Haskins²⁹ performed 2,100 tests on 1,145 patients. Of these, 220 tests were on healthy women. They found that in abortions without infection, the sedimentation rate returned to normal, 15 days after curettage. They further noted that in eight cases of ruptured ectopic pregnancy, the sedimentation rate was increased, but in no case was it as high as in acute or subacute salpingitis. The difference, however, was not sufficient to regard this as a differential test between the two conditions. They found normal rates in 40 cases of trichomonas vaginalis vaginitis, 13 cases of Frohlich's syndrome, and 80 cases of cystocele, rectocele, retroversion and prolapse of the uterus, but the rate was definitely elevated in 23 cases of infection of Skene's or Bartholin's glands.

Lesser and Goldberger³⁰ reported 2,000 cases of all conditions with 3,000 readings. They felt that it was even possible to differentiate acute appendicitis from acute rheumatic fever with abdominal symptoms, by

means of this test. The latter had a very high, while the former had an absolutely normal reading. They included 75 cases of acute appendicitis made up of catarrhal, gangrenous and suppurative, and observed that uniformly the sedimentation rate was normal, regardless of the pathologic lesion noted. On the other hand, all other types of acute surgical conditions in the abdomen, including ruptured appendix, gave an elevated reading.

Rubin²⁵ concluded that in surgery, the sedimentation rate is a more reliable indication of the condition of the patient than the temperature chart. Nystrom and Geisheimer,³¹ in reporting 57 gynecological cases, and Smith, Harper and Watson²⁸ feel that the sedimentation test gives more valuable information than the temperature chart or the white blood count.

On the other hand, Simmich,³² after an observation of 150 gynecological patients, of whom 132 had laparotomies, stated that the sedimentation rate was not a reliable guide in the determination of the safe operative time, and Williams³³ concluded after his study that the temperature curve and the study of the leukocytes remain as more stable indices for diagnosis and prognosis. Peterman and Seeger,³⁴ in reporting 150 cases in children, were of the same opinion.

From our studies, we are inclined to disagree with the views of this latter group. We observed 73 cases, which were normal in every respect and which had a normal sedimentation time but in whom the white blood count was over 10,000 in each case. Of these 73 cases, 19 had white counts of over 13,000 and in seven of these, the white blood count was over 16,000.

In 70 of these cases, the differential count was normal. One of these cases was especially interesting. The patient, a man of 42 years of age, had evidence of myocardial damage. He continued to have fever and leukocytosis for several months, during which time the sedimentation rate remained absolutely normal. Very careful investigation revealed no evidence of infection, and after a time the fever and leukocytosis disappeared (Table 1).

TABLE I

The laboratory records of a patient showing fever and leukocytosis together with a normal sedimentation rate

Date	Hb	R B C	Sed Rate	W B C	Diff	Temp
3/11/35	90	4,560,000	8	12,300	Normal	99.4
3/20/35	88	4,620,000	7	11,900	Normal	99.1
4/8/35	88	4,640,000	8	10,150	Normal	99.0
4/24/35	90	4,720,000	6	12,900	Normal	99.2
5/5/35	87	4,670,000	8	17,400	Normal	98.4
5/20/35	89	4,700,000	8	16,200	Normal	99.0
6/5/35	86	4,680,000	7	11,950	Normal	99.1
6/24/35	88	4,800,000	8	10,250	Normal	99.1
7/1/35	89	4,840,000	6	11,200	Normal	99.2
8/13/35	90	4,750,000	3	8,600	Normal	99.0
9/3/35	87	4,680,000	5	13,700	Normal	98.4
9/13/35	89	4,320,000	8	17,200	Normal	99.0

Malignant growths, if extensive, usually give a high sedimentation rate,

while a slow growing benign tumor without necrosis gives a normal rate. However, after irradiation of any tumor, the rate of sedimentation increases, probably due to decomposition of the tumor, with a resultant increased amount of foreign protein in the blood. According to Schiller,³⁵ if a malignant growth be removed operatively, the sedimentation rate should return to normal within six weeks, if complete removal was obtained. If the rate returns to normal, and remains normal at least six months, one may give a guardedly favorable prognosis. If the rate becomes abnormal within this time, it is suggestive of local recurrence of the growth or metastasis. In one of our cases, the patient, a woman of 62, had what appeared to be a typical fibroid, about the size of a grape fruit. The hemoglobin was 85 per cent, r b c 4,730,000, w b c 6,750, and the differential count was normal. The sedimentation rate, however, instead of being the normal as in a simple fibroid, was 32. The uterus when removed appeared grossly to be a fibroid, but on closer microscopical examination, malignant degeneration was found to have occurred at the central part of the tumor. Two months after the operation, the sedimentation rate was 8. There were seven other cases of malignancy in our group, with 19 determinations, all of which were over 28 millimeters. Four of these were carcinoma of the stomach, and in each the hemoglobin was over 65 per cent. It is interesting to note that, on the other hand, there were 11 cases of definite duodenal ulcers with a total of 28 determinations, and in not one did the readings go over 6 millimeters. Four of the cases had hemoglobin lower than 65 per cent.

One of the greatest uses for this test is in determining the degree of certain infections. If the infection be in the active state, the rate will be high, while if the infection be in the arrested state or state of repair, the rate will be low. It has been especially useful in infectious arthritis and tuberculosis. Oppel, Meyers and Keefer³⁶ studied 107 patients with various forms of arthritis and 103 with a miscellany of diseases, as a control group. They found a great variation in the sedimentation rate in different types of arthritis, the most rapid rate being in acute rheumatic fever, rheumatoid and gonorrheal arthritis. In our series, there were 23 readings made on nine patients with acute arthritis. In each the rate was elevated, ranging from 26 millimeters to 48 millimeters. An interesting observation is the uniformity of this test over a long period of time, as compared with the marked variability of the white blood count. (Table 2)

TABLE II
A case of acute arthritis illustrating the relative constancy of the sedimentation rate

Date	Hb	R B C	Sed	W B C	Polys
10/15/34	85	4,340,000	38	10,600	74%
11 15/34	80	4,130,000	33	13,350	76%
12/14/34	80	4,000,000	32	12,300	73%
1/15/35	82	4,730,000	36	10,000	74%
2/23/35	82	4,600,000	34	12,400	71%
3/23/35	86	4,920,000	36	7,600	73%
4/18/35	80	4,250,000	35	10,850	70%

Furthermore, as the patient improves, there is a tendency for the sedimentation rate to decrease (Table 3)

TABLE III

Case illustrating parallelism of clinical improvement and decrease of sedimentation rate

Date	Hb	R B C	Sed	W B C	Differential	General Condition
7/24/35	91	4,480,000	39	9,700	Normal	Bed-ridden Painful swollen feet
9/ 8/35	90	4,670,000	24	7,200	Normal	Bed-ridden Feet not so red
9/25/35	90	4,600,000	8	9,950	Normal	Ambulatory Feet not so red or painful
10/10/35	92	4,650,000	5	10,100	Normal	Feet much better Condition greatly im- proved

This is not only true in arthritis, but also in other infections Table 4 represents the findings in a patient of 14, with acute endocarditis, who showed simultaneous improvement in his clinical condition and in the sedimentation rate

TABLE IV

Case of rheumatic carditis showing clinical improvement and decreasing sedimentation rate

Date	Hb	R B C	Sed	W B C	Differential	General Condition
8/13/35	83	4,430,000	36	7,300	Normal	Bed-ridden, dyspnea, pain
9/ 3/35	85	4,460,000	25	6,000	Normal	Bed-ridden Slower pulse
9/16/35	82	4,310,000	14	11,650	Normal	Bed Less dyspnea
10/ 1/35	83	4,300,000	7	6,850	Normal	Sitting up No fever or pain
10/15/35	86	4,510,000	5	10,300	Normal	Ambulatory, much im- proved

In tuberculosis infections the sedimentation rate is high in the presence of activity and normal in the arrested stage The value of this test in tuberculosis has been widely recognized, especially in the European clinics In certain Austrian tuberculosis sanatoria, a sedimentation test is made routinely three times a week on each patient The usefulness of the test in this field is emphasized by Grafe³⁷ who reported 500 cases, Rubin,³⁸ Van Antwerp,³⁹ Cutler and Cohen,⁴⁰ Banyai and Anderson,⁴¹ Ringer⁴¹ and others Cutler and Cohen believe it to be 94 per cent accurate in tuberculosis They point out that a higher reading is obtained if the patient is unduly excited Banyai and Anderson, in 2,000 cases, found a normal sedimentation time in 128 cases with signs of activity, an error of 7.35 per cent They feel that the test's greatest value is in its use as an objective measure of the course of the disease It serves as a sensitive indicator of complications or the development of new foci, and as a criterion of results obtained

by a regimen or a specific treatment. New foci in lung tissue are sometimes not suspected, and complications like intestinal or renal tuberculosis are often not detected until an increase in the sedimentation rate has led to a careful search. It offers an approximate gauge of the extent of improvement when physical or roentgen examination may be of little value. Ringer pointed out that a rise in the rate in a tuberculous patient may precede hemoptysis. His two years experience with the test has convinced him that the test is one of real value. It reinforces physical, radiological and symptomatic evidence, and frequently presages oncoming trouble. He emphasized the fact that no tuberculous patient should be discharged until the sedimentation rate is normal. In our small series, we had six arrested cases of tuberculosis, none of which had a sedimentation time of over 7 millimeters, and one active case with a rate of 39.

In addition to these, there are other uses for this test as mentioned by Sivinsky,⁴² Tulipan and Director. Recently attention has been drawn to its usefulness in cases of coronary occlusion. In this condition the rate becomes elevated a few hours after the onset of the attack. The increase is probably due to the absorption of necrotic tissue from the produced myocardial infarct. After reaching its peak, the rate gradually diminishes. The duration of this period of elevated rate may serve as a guide in determining how long the patient should be kept at rest. It may therefore prove useful not only as a diagnostic measure, but also as a measure of the healing of the infarct. (Table 5)

TABLE V
The sedimentation rate following coronary thrombosis

Patient	Sed Rate prior to Attack	1st Wk of Attack	3rd Wk of Attack	4th Wk of Attack	5th Wk of Attack	6th Wk of Attack	12 Wks after Attack

C S	—	45	36	21	15	8	—
A G	—	48	—	—	—	—	—

SUMMARY AND CONCLUSIONS

1 The sedimentation test is a relatively simple laboratory procedure which is now soundly established as a valuable addition to our diagnostic armamentarium.

2 The sedimentation test is not a specific diagnostic test for any one condition, but the presence or absence of an increased sedimentation rate may have great value in differential diagnosis.

3 The comparison of repeated sedimentation tests is particularly useful in estimating the progress of disease. The test is now widely employed

in this manner in gynecological diseases, in tuberculosis, in rheumatic infections, in malignant growths and recently in coronary occlusion

4 The results obtained in 488 sedimentation tests on 395 patients were found confirmatory of the reliability of the test. Charts furnishing examples of the utility of the test are included. The results obtained with the test in six cases of coronary occlusion are tabulated

CLINICAL EXPERIENCES WITH REDUCED DOSES OF THEVETIN ORALLY ADMINISTERED ~

By EINAR R. DANIELS, M D , and WILLIAM S. MIDDLETON, M D ,
F A C P , *Madison, Wisconsin*

CLINICAL studies of the action of thevetin^{1,2} have amply confirmed the pharmacologic results of Chen and Chen^{3,4} and established its reliable digitalis-like effect in man. The pulse is slowed, evidences of decompensation are alleviated, diuresis ensues and characteristic electrocardiographic changes occur when thevetin is given either by the oral or the parenteral route. Its untoward by-effects also parallel those of digitalis with a singular deviation in the gastrointestinal action. Here intestinal effects (cramps and diarrhea) in the main replace the common gastric upsets (anorexia, nausea and vomiting) incident to digitalis intoxication.

The galenical preparations of the defatted be-still nuts, which are the source of the glucoside, thevetin, gave practically constant evidences of gastrointestinal irritation¹. Indeed, this action was so serious as to preclude their further clinical trial. On the other hand the glucoside, thevetin, parenterally or orally administered, proved a distinct improvement over the galenical products in this respect^{1,2}. Even with thevetin, however, 16 of 40 patients with cardiac decompensation showed some gastrointestinal effects². Of this group 11 patients after a period of rest were able to resume the use of the drug without a recurrence of abdominal symptoms. The failure of concurrently administered belladonna to control the cramps and diarrhea caused by thevetin argues against Chopra and Mukerjee's suggestion that these phenomena are due to peripheral vagal action⁵. Furthermore, atropinized intestinal strips from the rabbit show vigorous contraction upon the application of thevetin².

A re-survey of the situation² evolved certain illuminating circumstances. The minimal emetic dose of thevetin is equivalent to 35 per cent of the cat unit as compared with 50 per cent for ouabain. Intestinal strips of rabbits are stimulated by minimal concentrations of thevetin and ouabain in the ratio of $3\frac{1}{3}$: 1 as compared with the ratio of cat unit values of 7 : 1. In other words one may expect gastric and intestinal effects much more promptly in relation to the cat unit with thevetin than with ouabain. Clearly, too, the intestinal action of thevetin may be expected to precede its effect on gastric function.

On the other hand a maximal bradycardia is induced with 30 per cent of the cat unit of thevetin as compared with 58 per cent for ouabain. Accordingly it seemed reasonable to anticipate an optimal clinical advantage with one half the cat unit dosage of thevetin as compared with ouabain. Since

the earlier results indicated the appearance of a digitalis-like action from thevetin before theoretical tolerance on the body weight basis, such a readjustment of dosage seemed justified. At the same time the suggested reduced doses of 1 cat unit, three times a day, with a maintenance dose of 1/3 cat unit, three times a day, (as a maximum), offered the further prospect of an evaluation of the possible effect of such a reduction of dosage upon the incidence of untoward gastrointestinal symptoms.

A group of 25 patients with cardiac decompensation was subjected to this revised program of reduced thevetin dosage. In table 1 are listed their several diagnoses and the pertinent clinical data, particularly relating to therapy, and the results therefrom.

Turning to the results of treatment, under "Symbolic Value of Thevetin Therapy," there will be found a rough assessment of therapeutic response.

TABLE II
Initial Effect of Thevetin

	CLINICAL OBSERVATIONS	Total Cases	CASE NUMBERS
CIRCULATORY ADVANTAGE	Subjective, only	0	
	Objective, only	3	3, 4, 14
	Both, combined	19	2, 5, 6, 7, 8, 9, 10, 12, 13, 15, 16, 17, 18, 19, 21, 22, 23, 24, 25
ADVERSE ACTION	Gastric symptoms, only (anorexia, nausea, vomiting)	0	
	Intestinal symptoms, only (cramps, diarrhea)	1	11
	Both gastric and intestinal symptoms	2	1, 20

Obviously 18 patients responded favorably to the alcohol solution of thevetin given by mouth and in one further patient (case 14) there was a good result with but slight diarrhea. In two patients (cases 4 and 6) the circulatory advantage did not compensate for the adverse gastrointestinal symptoms. Finally in three patients (cases 1, 11 and 20) the severity of the gastrointestinal disturbance seriously outweighed the action upon the circulation. While case 16 escaped gastrointestinal disturbances, there was no maintained circulatory advantage.

To throw further light on the problem of the balance between therapeutic advantages and the toxic drawbacks in the use of thevetin it was thought important to analyze the clinical data in this group of patients from the standpoint of the initial effect of the drug. This analysis is presented in table 2. At a glance it will be seen that in only three patients (cases 1, 11 and 20) did the toxic manifestations anticipate the therapeutic action of

the drug Interesting though this circumstance may be, it loses some of its significance when the necessity for a protracted action in this group of patients is called to mind Hence a summary of the ultimate effects of thevetin therapy is shown in table 3

It will be seen from this table that 19 of the 25 patients experienced a desired circulatory response from the oral use of reduced doses of thevetin and that two patients (cases 4 and 6) were assessed as doubtfully improved In the remaining four (cases 1, 11, 16 and 20) no appreciable advantage from the use of the drug was observed These results are comparable with those obtained when the routine of the Eggleston tolerance dosage was conformed to in the use of thevetin² More interesting is the analysis of the adverse reactions under the reduced scale of dosage Here it appears that 18 of the 25 patients were free from untoward symptoms and seven experi-

TABLE III
Summary of Ultimate Effects of Thevetin from Table I

	CLINICAL OBSERVATIONS	TOTAL	CASE NUMBERS
CIRCULATORY CONDITION	Improvement	19	2, 3, 5, 7, 8, 9, 10, 12, 13, 14, 15, 17, 18, 19, 21, 22, 23, 24, 25
	Doubtful improvement	2	4, 6
	No response	4	1, 11, 16, 20
UNTOWARD SYMPTOMS	Symptoms absent or negligible	18	2, 3, 5, 7, 9, 10, 12, 13, 15, 16, 17, 18, 19, 21, 22, 23, 24, 25
	Gastric symptoms, only (anorexia, nausea, vomiting)	0	
	Intestinal symptoms, only (cramps, diarrhea)	3	8, 11, 14
	Both gastric and intestinal symptoms	4	1, 4, 6, 20

enced either intestinal distress or intestinal and gastric disturbances In two patients (cases 8 and 20) diarrhea was controlled upon lowering the dosage of thevetin In a third (case 14) the circulatory advantage was maintained, but the glucoside was eventually discontinued upon the occurrence of a slight diarrhea (without recourse to the simple expedient of lessening the dose) Obviously then in only four instances (cases 1, 4, 6 and 11) may thevetin be charged with adverse gastrointestinal effects of such degree as to preclude its continued use and in each instance it will be observed that cramps accompanied the diarrhea It has been our experience with larger, as well as with reduced doses of thevetin that a mild diarrhea constitutes no sound objection to the continuance of the drug Indeed, there may be some advantage through the reduced physical effort of defeca-

tion Moderate to severe diarrhea and cramps, however, constitute as serious handicaps as do nausea and vomiting

When compared with the adverse results of thevetin therapy under an Eggleston regimen of dosage by body weight,² there is a distinct advantage in favor of the reduced doses Twenty-four of the earlier group of 40 patients (60 per cent) were free from symptoms as compared with 18 of 25 patients (72 per cent), in the present group Obviously the reverse of the picture is true, namely a higher incidence of gastrointestinal symptoms on the larger doses of thevetin than with schedule of reduced doses (40 per cent against 28 per cent) Apparently there is an individual idiosyncrasy to thevetin particularly in the occasion of intestinal cramps and this circumstance determined a small group in this series of patients, as well as the earlier groups, to whom thevetin was denied for this reason alone

The therapeutic-toxic ratio of digitalis-like drugs is so important that a search of the literature was made for studies of this type upon digitalis itself Generalities were found to prevail, but Bastedo⁶ reported a 35 per cent incidence of toxic symptoms among 90 patients receiving digitalis in Bellevue Hospital Whereupon Shanahan⁷ undertook an analysis of the matter from the materials in the records of the Wisconsin General Hospital A careful selection of materials was made to exclude those with prior digitalis therapy, inadequate control observations or other confusing factors Among a group of 65 patients with cardiac decompensation thus culled from a large series, he found that 37 per cent showed some evidence of digitalis intoxication at one time or other Furthermore 28 per cent of these 65 patients developed symptoms of the toxic action of digitalis before any circulatory advantage was attained Finally 22 per cent of the group showed such serious reactions to digitalis as to preclude its continuance

These figures are not quoted in extenuation of the untoward results from thevetin therapy Apparently a reduction of the dosage of this glucoside by mouth commensurate with its superior vagal effect has induced a lessening of the gastrointestinal action Nevertheless cramps and diarrhea do occur in an appreciable percentage of cases even under reduced doses In some of these, the adverse effects do not outweigh the circulatory advantage incident to the use of thevetin In others, the toxic symptoms preclude further use of the drug On the other hand in cardiac cases that do not tolerate digitalis well thevetin may offer the boon of a further reliable cardiac glucoside Moreover as has been reported earlier¹ thevetin possesses distinct advantages as a drug for emergency use by intravenous injection

THE DIAGNOSIS AND TREATMENT OF HYPER-INSULINISM *

By SEALE HARRIS, M D , F A C P , *Birmingham, Alabama*

THE recently recognized disease entity, hyperinsulinism, is being diagnosed with increasing frequency. Cases have been reported in practically every country in the world in which medical journals are published. It is interesting to observe the influence of American medical literature on clinical practices in foreign countries, and it is pleasing to note that, in nearly all the articles on hyperinsulinism and spontaneous hypoglycemia in foreign journals, the authors have been generous in their references to contributions on the subject by American physicians.

Among the many foreign clinicians who have reported cases of hyperinsulinism, or spontaneous hypoglycemia, or have published articles on the subject, may be mentioned Cammidge (1924 and 1930), Cameron (1930), Wauchope (1933), Cairns and Tanner (1933), of England, Moore, O'Farrell and Malley (1931), of Ireland, Sippe and Bostock (1933), of Australia, Posel (1933), of South Africa, Gougerot and Peyre (1925), Sendrail and Planques (1927), Laroche, Lelourdy and Bussiere (1928) and Sigwald (1932), of France, Krause (1930), Roth (1930), Wilder, Josef (1930) and Rosenberg (1932), of Germany, Bakser (1933), of Poland, Federoff (1931), of Russia, Stenstrom (1926), Sjogren and Tillgren (1927), Hagedorn (1932), Ehrstrom (1932), of Scandinavia, Massa (1929), Reale (1929), Lami (1930), Cimmino (1931), and Tarsitano (1931), of Italy, Zubirian (1929), of Mexico, and Valenzuela (1931), of Chile.

Hyperinsulinism Consciousness "Hyperinsulinism takes another syndrome from the waste basket of neuroses" is the syllogistic statement of Evans and McDonough, of LaCrosse, Wisconsin, who found and relieved six cases in six months' private practice after they became "hyperinsulinism conscious."

Powell, a general practitioner of West Monroe, Louisiana, found 25 cases of hyperinsulinism in two years after he recognized his first case. He concludes "Ample case reports are now in the literature to show that hyperinsulinism causes symptoms varying from drowsiness to narcolepsy, from vertigo to epilepsy, and from mental deficiency to mental degeneracy. Unfortunately all the cases are not in the literature—they are to be found in every doctor's clientele and, sad to relate, are most probably untreated."

Wilder, Allen, and Robertson, in 1927 made autopsy studies of an inoperable case of hyperinsulinism due to an islet cell carcinoma, and proved the pathological basis for the condition. Since then Wilder, Allen, Judd,

* Read before the Nineteenth Annual Clinical Session of the American College of Physicians, Philadelphia, Pennsylvania, May 3, 1935

Rowntree, Ryneerson and their associates have reported a number of cases, most of which have been operated upon. Wilder called attention to the erroneous diagnoses as applied to hyperinsulinism, including "nerves, neuasthenia and hysteria." He adds "Hypoinsulinism and hyperinsulinism are in fact clinical antitheses the latter is of as serious significance as the former, and the practitioner of today must be as familiar with one as with the other."

Marsh, of Madison, Wisconsin, who reported eight cases of mild hyperinsulinism in 1931, regards the condition as of frequent occurrence. Tedstrom, of Santa Ana, California, reported four cases and analyzed the literature on 64 other cases in 1933. In 1935 he states that he has had about 100 cases of hypoglycemia, most of which are due to hyperinsulinism.

It is not an accident that Carr, Parker, Larrimore, Graham, Womack, Marriott and their associates in Barnes Hospital (Washington University) in St. Louis, since 1930 have diagnosed and have removed five islet adenomas, and have performed three resections of the pancreas for hyperinsulinism, thus relieving patients of otherwise hopeless conditions. One of the most dramatic cases in surgical literature is Everts Graham's first subtotal pancreatectomy in a 15 months old baby, whose condition was hopeless because of mental deterioration and convulsions due to hyperinsulinism. The child has had no convulsions since the operation and his mentality, as studied by scientific tests, has improved 40 to 50 per cent. Graham and Womack are impressed with the neuro-psychiatric manifestations of hyperinsulinism. After discussing various symptoms they conclude "It is important to emphasize that in many cases the neurological and psychiatric aspects of the condition are so prominent that many of the patients with chronic hypoglycemia have been referred primarily to neurologists and psychiatrists for treatment."

About one year ago Whipple in the Presbyterian Hospital, New York, removed an islet cell adenoma from a patient who had recurring attacks of unconsciousness, and other nervous and psychic phenomena, associated with hypoglycemia, with dramatic relief of symptoms. When the staff of the Neurological Institute of the Presbyterian Hospital became "hyperinsulinism conscious" they found five similar cases upon which Whipple operated with clinical cures. Thus six persons, who were doomed to institutional lives as psychotics, or to die in hypoglycemic coma, were restored to health by the cooperation of the neuro-psychiatric and surgical staffs of one hospital. No doubt there are as many cases of hyperinsulinism passing, unrecognized and unrelieved, through the wards of every other large hospital in the country as were diagnosed and cured at the New York Presbyterian Hospital during the last 12 months.

Winans in Dallas, Texas, and Waters in Atlanta, Georgia, have reported a number of mild cases of hyperinsulinism which they relieved by dietary management. Winans in a recent paper on insomnia called attention to hypoglycemia as one of the causes of sleeplessness.

In Toronto, Howland, Campbell, Maltby, and Robinson in 1929 made the first preoperative diagnosis of an islet tumor, the removal of which cured the patient of convulsions due to "dysinsulinism" Rabinowitch, in Montreal has reported five cases of hyperinsulinism Goldzieher of New York recently reported 200 cases of spontaneous hypoglycemia Many other cases have been reported by American clinicians, and many more have been recognized and treated by physicians who have become "hyperinsulinism conscious" but have not reported their cases

Cammidge, of London, stimulated by his recognition of two cases of "chronic hypoglycemia" in 1924—an observation that no doubt was independent of the work done by others—found 198 additional cases before 1930, an average of 33 cases a year The fact that Cammidge has reported more cases of spontaneous hypoglycemia than all the other clinicians in the British Empire means simply that he learned to recognize the symptoms due to hypoglycemia and clinched his diagnoses by finding low blood sugars However, a number of cases have been reported by other British clinicians Sippe and Bostock in Brisbane, Australia have reported 30 cases of chronic hypoglycemia They regard the condition as being almost, if not quite, as frequent as the opposite condition, diabetes mellitus (hypoinsulinism) They observed hypoglycemia in 0.47 per cent of their patients, while diabetes was diagnosed in 0.51 per cent

Recently Sippe reported five cases of hypoglycemia associated with angina pectoris Cardiographic studies and blood sugar determinations showed correlation of the cardiac symptoms to hypoglycemia The cardiac attacks were prevented, or relieved, by a diet that maintained, or raised, blood sugar levels above the point at which the cardiac manifestations of hypoglycemia appeared

Personal Cases From March 1923 to May 1935 I have made the clinical diagnosis of hyperinsulinism in 119 cases, an average of 9.9 cases a year In a number of these cases the diagnosis of hyperinsulinism was made by other physicians before they referred them to us for treatment In none of these cases could we find evidence of any liver disorder that could cause hypoglycemia, though in several cases there were manifestations of dyspituitarism, in the stage of hypofunction, hypothyroidism and hypo-adrenalism which seemed to have been the primary cause of the relative, or actual, hyperinsulinism responsible for the hypoglycemic symptoms

Without question many hypoglycemic patients pass, untreated and unrelieved, through the hands of capable clinicians, because they have not become "hyperinsulinism conscious" The opinions of a number of physicians, who have had experience in dealing with hyperinsulinism, have been cited to prove that the condition, or disease entity, must be reckoned with by the medical profession It therefore seems timely to discuss the diagnosis and treatment of hyperinsulinism

Anamnesis Evidence favoring the diagnosis of hyperinsulinism may sometimes be elicited in patients who complain of "spells" of various kinds.

by inquiring as to whether the attacks occur during the night, before breakfast, or several hours after meals. If such is the case and if the patient's symptoms are relieved by taking a soft drink, fruit, or milk, or other food between meals, and if the patient feels distinctly more comfortable after meals, one would suspect hyperinsulinism. My early cases were of that type. Sometimes, however, the hypoglycemic attacks seem to occur at meals, at the sight of food, or immediately after leaving the table before there is time for digestion and assimilation of carbohydrates and when the blood sugar is still low.

Hyperinsulinism has been called the "hunger disease," because excessive appetite and the desire for food between meals are present in most cases. Sometimes, however, the patient with hyperinsulinism becomes nauseated when the attacks of weakness, nervousness and even unconsciousness occur. The patient may also complain of abdominal discomfort, relieved by taking food, his symptoms thus resembling those of gastric or duodenal ulcer. Several such cases in which operation for peptic ulcer had been considered have come under my observation.

Hunger and relief of symptoms by eating are not sufficient evidence to warrant a diagnosis of hyperinsulinism. I have seen two cases of pronounced bulimia, one in a hysterical woman and another in a mild psychotic, who obtained temporary relief from eating, but whose glucose tolerance blood sugar curves were normal.

A history of over-indulgence in sweets of all kinds is frequent in patients with hyperinsulinism. Not infrequently the victim of this condition has learned that he can relieve his symptoms by eating sweets and he devours candy and various "nick nacks," between meals to keep off attacks. After a time sweets give relief for only a few minutes. Often such patients will voluntarily mention that they "crave sweets." Occasionally hyperinsulinism patients will go on "sugar sprees" when they will eat inordinately of cakes, candy, pies, ice cream and other cane sugar products for a few days. Usually their symptoms are aggravated by such overindulgences.

Overindulgence in Sweets and in Caffeine Beverages My first case of hyperinsulinism observed 12 years ago gave a history of overindulgence in caffeine beverages. Since then the history of taking coca-cola, or coffee, between meals for the relief of the attacks of hypoglycemia, or to prevent them, has occurred too frequently not to have a relationship of cause and effect, at least the symptoms are exaggerated by the frequent use of soft drinks between meals. The caffeine soft drinks relieve the symptoms temporarily, first, by supplying a soluble carbohydrate that is rapidly absorbed and metabolized, and second, as Womack suggested, probably by the stimulation of the adrenals by caffeine, thus raising the blood sugar level above the point at which the hypoglycemic symptoms occur.

A good therapeutic test for hyperinsulinism is to give the patient a glass of coca-cola, or a cup of coffee without cream, during an attack, or before the suspected attack. If it relieves the symptoms temporarily or prevents

the attacks, hyperinsulinism may be suspected. Certainly there is not a better or quicker acting remedy for an attack, or for symptoms of hypoglycemia, than a glass of coca-cola or other caffeine-containing soft drink, or a cup of coffee, with sugar but without cream. The regular excessive use of the caffeine beverages, however, seems to exaggerate the hypoglycemia in patients with hyperinsulinism.

Gastrointestinal Manifestations The gastrointestinal manifestations of hyperinsulinism are frequent and varied. A considerable proportion of the patients who have hypoglycemic symptoms associate their discomfort with food. Often they feel that certain articles of food they had eaten previous to attacks were responsible for their symptoms. Many such patients complain of hunger, but sometimes they suffer from sitophobia because of the fear that eating will make them worse.

Many patients who have come to our clinic complaining of "nervous indigestion," or with a previous diagnosis of "irritable colon," have been found to have hypoglycemia that synchronized with their symptoms, and have been relieved by a diet planned to keep blood sugar levels within normal limits. Other patients, with actual duodenal ulcers, have had associated nervous symptoms which were proved to be due to hypoglycemia. It, therefore, should be remembered that hyperinsulinism may coexist with actual lesions of the stomach and other abdominal viscera.

Cambridge in reporting 200 cases of "chronic hypoglycemia" said "Comparatively few cases of hypoglycemia are free from gastrointestinal disorders." Sippe and Bostock mentioned gastrointestinal symptoms in 18 of 25 reported cases of "chronic hypoglycemia," most of them mild cases that were promptly relieved by dieting. Many other clinicians have reported cases of hyperinsulinism, or chronic hypoglycemia, in which gastrointestinal symptoms were present.

Dextrose tolerance tests, carried out for six full hours, in patients with complaints referable to the gastrointestinal tract, associated with nervousness and weakness, may reveal hypoglycemia as the cause of the symptoms.

Abdominal Pain Evarts Graham observed abdominal pain in his first case of islet cell adenoma of the pancreas. The patient had had his appendix removed without relief from the abdominal pain. Abdominal pain, however, is by no means a constant symptom in the severe cases of hyperinsulinism with, or without, adenomas of the pancreas. Womack writes "In two of eight cases, five adenomas of the pancreas and three resections successfully operated upon in Barnes Hospital, pain in the abdomen was outstanding. A cholecystectomy was done in one elsewhere and an appendectomy in the other with no relief. This cramp-like pain disappeared with the relief of the hypoglycemia." Undoubtedly many unnecessary and unsuccessful abdominal operations have been performed upon hyperinsulinism patients.

The location of the pain is important. In the cases of hyperinsulinism that I have seen, in which abdominal pain was a symptom, the pain was in

the mid-portion and upper left quadrant of the abdomen. In most of them there was tenderness on deep pressure in the same locality, i.e., over the pancreas. Periodicity of the pain, usually more pronounced when the stomach was empty, was present in a number of cases. Partial resections of the pancreas relieved the pain in three of my cases.

Attacks of Convulsions and Unconsciousness The most important manifestations of the severe types of hyperinsulinism are attacks of unconsciousness and convulsions. Most of the patients with hyperinsulinism who have been operated upon have had varying periods of unconsciousness, with and without convulsions, and many of them have been diagnosed as epilepsy, until blood sugar studies proved the presence of a sufficient degree of hypoglycemia to account for the convulsions and unconsciousness.

Convulsions do not occur in all severe cases of hyperinsulinism. Frequently attacks of unconsciousness resembling diabetic coma occur. Several cases of death in hypoglycemic coma without convulsions have been reported and the diagnosis was proved by finding at autopsy tumors of the islands of Langerhans.

The unconsciousness following hypoglycemic convulsions lasts from a few minutes to several hours. In one case of repeated convulsive attacks, in which the patient was in what was called "hypoglycemic status epilepticus" a clinical cure resulted from the removal of a carcinoma of the islands of Langerhans (Bast, Schmidt and Sevringhaus). Often patients with hyperinsulinism awaken voraciously hungry after convulsions, but not always, because nausea and vomiting sometimes follow hypoglycemic attacks.

Hysterical and Psychotic Manifestations Many patients who have been regarded as hysterical, or psychasthenic, have been proved to suffer from hyperinsulinism, and have been clinically cured by regulation of the diet.

Actual psychotic symptoms may occur in the severe cases of hyperinsulinism. The woman, reported by Finney and Finney, had "crazy spells" when she would do queer things. She was found to have a blood sugar of 0.030 per cent. Graham and Womack reported cases in which patients with hyperinsulinism had actual psychoses which subsided after removal of islet cell adenomas of the pancreas. Many other clinicians have observed psychotic patients who had hyperinsulinism.

Powell suggests that the protean nervous manifestations in hyperinsulinism are due to a deficiency of glucose in the blood supply of the brain. He cites a recent editorial in the *Journal of the American Medical Association* to the effect "that the brain lives exclusively on a sugar diet and that the quantity thereof may readily be determined by various blood sugar and glucose tolerance tests." Zeigler says that spontaneous hypoglycemia will cause insomnia and maniacal delirium.

DIAGNOSIS

A positive diagnosis of hyperinsulinism either of the mild or severe type cannot be made without fasting blood sugar studies and glucose tolerance tests proving the presence of hypoglycemia in a patient with symptoms of hyperinsulinism

Routine fasting blood sugars on my patients for the last 12 years have shown hypoglycemia in many whose history did not suggest hyperinsulinism, but who, on more careful questioning, gave definite hypoglycemic symptoms. In my first case of epilepsy associated with hyperinsulinism the diagnosis was not suspected until his fasting blood sugar, taken as routine, was found to be 0.060 per cent. Attention having been called to the low fasting blood sugar in this case, further questioning brought out a history of hypoglycemic symptoms, and then a glucose tolerance test showed a low flat hyperinsulinism curve.

Repeated Blood Sugar Studies One fasting blood sugar or one glucose tolerance test is not always sufficient to warrant a positive diagnosis of hyperinsulinism since there seem to be periods when the hyperinsulinism patient will have normal blood sugar readings, even though at other times he has shown marked hypoglycemia. Cushing observed in hyperpituitarism that there are undulations, or waves of accelerated hypophyseal secretion, and it is quite evident that in hyperinsulinism there are quite marked variations in islet cell secretion.

The factor of mental and physical fatigue affects blood sugar levels. In making glucose tolerance tests, ambulatory patients should not be permitted to lie down, but should, if possible, take about the same amount of exercise that they ordinarily take when the attacks have occurred. I have observed repeatedly in patients taking the glucose tolerance test that when the blood sugar levels became low, they had hypoglycemic symptoms which subsided when they lay down. After resting for a few minutes without taking food, the blood sugar readings were higher.

The occurrence of the symptoms complained of, at the stage of the test when the blood sugar becomes low, as frequently occurs, is presumptive evidence of hyperinsulinism. So likewise is the finding of a low blood sugar in blood drawn during a spontaneous attack. It, therefore, is advisable to get repeated blood sugar tests an hour before the noon and evening meals and after the patient has had several hours' work at his usual vocation at about the time symptoms usually occur. In studying patients with a history of epileptic or epileptiform attacks, blood sugar tests should be made at about the time of expected attacks, but it should be remembered that after generalized convulsions usually the blood sugar readings will be higher than before the paroxysm.

Gammon and Tannery suggested that in examining the patient suspected of having hyperinsulinism sufficient insulin be given to produce hypoglycemic reactions which in many cases will reproduce the patient's symptoms.

Since in many cases the same result may be accompanied by reproducing the symptoms in the hypoglycemic phase of glucose tolerance tests, the use of insulin as a diagnostic measure seems rarely indicated

The Six Hour Glucose Tolerance Test The glucose tolerance test should be carried out for six full hours in making the diagnosis of hyperinsulinism. I have observed a number of patients whose blood sugar readings were normal for four hours after the ingestion of the dextrose, but fell rapidly and to very low levels in the fifth and sixth hours. Recently a patient who had marked symptoms of hyperinsulinism and had shown a hyperinsulinism curve was given a glucose tolerance test in another hospital. The test was carried out for only four hours, the last reading having been 0.070 per cent, on this evidence the case was not diagnosed as hyperinsulinism. Four hours is long enough to carry out a glucose tolerance test for diabetes, but six or eight hours may be necessary in studying the case for suspected hyperinsulinism. If glucose tolerance tests were carried out for six hours, they might show, as they did in a few of my cases, a diabetic curve for three or four hours and hypoglycemic readings for the fifth and sixth hours.

Patients object to and sometimes refuse venipunctures for blood specimens every hour for six hours, and laboratory technicians sometimes get tired of running blood sugars, but unless the test is carried out that long, some cases of hyperinsulinism will not be diagnosed as such. Sometimes it is difficult to get into the veins in making glucose tolerance tests, and then it is best to get the fasting blood sugars and the blood sugar five and six hours after the ingestion of the dextrose.

Therapeutic Test If for any reason the patient cannot or will not have blood sugar studies made and if hyperinsulinism is suspected, a few days of rest on a relatively low carbohydrate diet consisting largely of the 5 and 10 per cent vegetables and fruits, with orange or tomato juice on arising and on retiring and every one or two hours between meals and when awake at night, may relieve the symptoms. If the patient is underweight, two to four ounces of cream may be given every three hours when awake. The cane sugar products and other soluble carbohydrates including soft drinks and candy between meals should be given only to relieve the attacks. On such a diet with sufficient rest, the patient with all but the most severe hyperinsulinism will be improved or completely relieved of his symptoms. If he is not relieved either his symptoms are not due to hyperinsulinism or blood sugar studies may show hypoglycemia of sufficient degree to demand exploration of the pancreas for an adenoma.

The Diagnosis of Hypoglycemic Coma It should be a routine in every case of unexplained unconsciousness to make a blood sugar determination at the earliest moment possible. Hypoglycemic coma is one of the frequent causes of unconsciousness, particularly when preceded by convulsions. Wanchope recommends the use of adrenalin hypodermatically, and dextrose intravenously in the cases in which there is the question of diabetic or hypo-

glycemic coma If the unconsciousness is due to hypoglycemia the adrenalin and the dextrose intravenously will bring the patient out of the coma in a few minutes, whereas if the patient continues unconscious a delay of 15 minutes while waiting for a blood sugar report will not affect the ketosis which usually can be relieved by the use of insulin

DIFFERENTIAL DIAGNOSIS

Every possible cause of hypoglycemia besides pancreatic disease should be considered, including studies of all the other organs of internal secretions, so as to exclude them as factors if possible, before making a diagnosis of uncomplicated hyperinsulinism

Since hyperinsulinism has been manifested by symptoms which have suggested hysteria, psycho-neurasthenia, neuro-circulatory asthenia, psychoses, brain tumors, epilepsy, narcolepsy, status epilepticus, epileptiform convulsions, appendicitis, gall-bladder infection, duodenal ulcer and many other diseases it is apparent that in the study of all patients presenting such symptoms blood sugar tests should always be included On the other hand the finding of hypoglycemia does not always prove that it is the cause of the symptoms We have had two cases of brain tumor in which hypoglycemic symptoms were pronounced

Hyperinsulinism is invariably associated with hypoglycemia It should be remembered, however, that in patients who have hypoglycemic symptoms, fasting blood sugars are not always low Therefore, repeated and varied blood sugar studies should be made before hypoglycemia is excluded in suspected cases of hyperinsulinism It should be remembered also that the patient with hyperinsulinism may have other diseases that may, or may not, affect the hypoglycemic symptoms Thus, two cases of hyperinsulinism in syphilitic patients have been observed in which anti-syphilitic treatment did not affect the blood sugar levels or the symptoms of hypoglycemia

Hypoglycemia from Extra-Pancreatic Disorders Cases of marked degrees of hypoglycemia due to organic diseases or functional disturbances of other organs besides the pancreas have been reported as having been due to (a) a deficient glycogenesis in the liver from poisons such as arsphenamine or other arsenicals, phenylhydrazine, phosphorus or other hepatotoxins (Cross and Blackford), and from massive tumor of the liver (Nadler and Wolfer), (b) inadequate mobilization of glycogen due to deficient secretion of the suprarenals (Anderson), (c) pituitary dysfunction (Josef Wilder), (d) thyroid dysfunction (Tedstrom) The case of Weil, in which the hypoglycemic convulsions occurred only during menstruation suggests that ovarian dysfunction may be a factor in some cases

It is of particular importance to exclude hypopituitarism, hypothyroidism, and hypoadrenalinism which may be the primary cause of the hypoglycemia that is responsible for the symptoms of hyperinsulinism The secretions of the hypophysis, thyroid and adrenals are antagonistic to, and therefore may control, the secretion of insulin,

TREATMENT

The problem of dieting in hyperinsulinism is much the same as in diabetes mellitus (hypoinsulinism) in that each patient has to be dieted to suit his particular needs. It is necessary to arrange a diet that will nourish the patient properly, providing sufficient amounts of carbohydrates, proteins and fats, with due consideration to its vitamin content. As far as the quantity is concerned, it should have a lower carbohydrate content than in diabetes, with sufficient calories to maintain normal body weight and physical vigor. The protein content should depend on the age and weight of the individual, we give from 60 to 75 gm. to an adult weighing 70 kilograms.

Theoretically, a high carbohydrate diet would seem to be indicated in hyperinsulinism, but John pointed out that carbohydrates stimulate the secretion of insulin and that when rapidly soluble carbohydrates such as sugars are given, they cause excessive insulogenesis, which continues after the carbohydrates are metabolized, with resulting hypoglycemia. John observed, in giving dextrose tolerance tests, that while the blood sugar level was high for the first one or two hours, it was followed by a rapid fall to a level much lower than the fasting blood sugar. I made the same observation independently after giving a dextrose tolerance test to my second patient with hyperinsulinism in 1923.

Weil's experience with his patient with dysinsulinism, who had recurring attacks of convulsions and unconsciousness, proves the fallacy of a diet high in soluble carbohydrates in insulogenic hypoglycemia. He found that a few hours after a high carbohydrate meal, the blood sugar reached a much lower level than the patient's fasting blood sugar. He was able to control the attacks of convulsions by placing the patient on a low carbohydrate, high fat diet with frequent feedings.

Shepherdson states that the blood sugar level will rise on a low carbohydrate, high fat diet. He quotes Weeks, Renner, Allan and Wishart as having observed in a study of epileptic patients on high fat diets that in every case they developed a hyperglycemia. It is possible that ingested fats may have a direct effect in inhibiting the secretion of insulin and that, in the cases of epilepsy associated with hypoglycemia in which the ketogenic diet has proved beneficial, perhaps in some cases the good effects have been due to a rise in the blood sugar level, rather than to the sedative action of the ketone bodies in the blood. Certainly in my hands a moderately low carbohydrate, high fat, moderate protein diet has given the best results in treating chronic hyperinsulinism.

Low Carbohydrate, High Fat Diets Early in my experience in dealing with hyperinsulinism I began using a low carbohydrate diet, consisting largely of 3, 5 and 10 per cent vegetables and fruits, combined with a high proportion of fats, with frequent feedings. I reasoned that the carbohydrates in the form of vegetables and fruits, which must be digested before being absorbed and metabolized would be released as dextrose in small

quantities at a time, and therefore, would not stimulate the secretion of insulin as much as meals made up largely of foods of high carbohydrate content, particularly those containing cane sugar products. Fats, particularly cream, were given with meals and between meals, with the idea that they are emptied slowly from the stomach. Therefore, the metabolism of the carbohydrates mixed with fats would be slow compared to the rapid emptying of the stomach and the accelerated metabolism after the ingestion of carbohydrate meals without fats.

Waters, basing himself upon the experimental studies of Sweeney, which showed higher blood sugar levels after high fat diets, and lower levels after high carbohydrate diets, and also upon his own experience in relieving cases of spontaneous hypoglycemia by a high fat, moderately low carbohydrate diet, concluded "A diet reducing the carbohydrate intake and increasing the volume of fats seems to diminish an excessive insulin production and to raise the blood sugar level."

Dieting the Hyperinsulin Individual The diet in each case of hyperinsulinism should be calculated to meet the patient's nutritional needs. The adult patient with hyperinsulinism, of average height and weight, should have about 2,250 calories, derived from 90 to 150 gm of carbohydrates, from 60 to 75 gm of proteins and the remainder from fats, largely cream and butter. The food intake is best divided into from five to seven feedings a day.

A number of my patients with hyperinsulinism have been overweight, and other clinicians have observed a number of obese patients with hyperinsulinism. In such cases the fats should be reduced, and a low caloric diet with food every two hours is indicated. In such cases I prescribe a diet of about 120 gm of carbohydrates, 60 gm of fat and 60 gm of protein (1,260 calories) divided into six or eight feedings a day. On such a diet the patient's activities should be restricted and the amount of carbohydrates should be increased to 150 to 200 gm, or even more if the patient is losing weight, or if he becomes weak.

In the underweight, asthenic patient with hyperinsulinism, a diet of 90 to 150 gm of carbohydrate, from 200 to 300 gm of fat, and from 60 to 75 gm of protein, divided into five or six feedings a day, will keep the blood sugar at a sufficiently high level to prevent hypoglycemic symptoms, and will build up the patient's general health and state of nutrition.

Careful blood sugar studies should be made on each patient for a few days after being placed on a diet for hyperinsulinism, during which time his food should be weighed and measured if possible. It is just as necessary to teach the patient with hyperinsulinism food values and to calculate and arrange the menus suited to his particular case, as it is to teach "diabetic arithmetic" to patients with hypoinsulinism (diabetes mellitus). The intelligent patient with severe hyperinsulinism usually becomes very much interested in "playing the game of dieting" because he has a holy dread of the attacks of unconsciousness, with or without convulsions.

It is essential to impress the patient with hyperinsulinism with the necessity of moderation in all things, particularly physical exercise. Studies on marathon runners by Levine and his associates showed that physical exhaustion produces physiologic hypoglycemia. A number of my patients have observed that their attacks of hunger, weakness and the like, and even petit mal and grand mal seizures, have occurred most frequently after physical exertion. The patient with hyperinsulinism should be taught all the rules of personal hygiene adapted to his particular needs, just as the diabetic patient is taught how to live and enjoy health even though he has the handicap of a crippled pancreas.

The Use of Bromides and Barbiturates in Hyperinsulinism The dietary management of hyperinsulinism, without medicines, usually is sufficient to control the disease and prevent hypoglycemic symptoms in the mild types and in many of the severe cases, yet drugs may be required at times in the more serious cases, particularly in those associated with epileptiform convulsions.

The rationale of the use of the bromides and barbiturates in epilepsy is considered to be their effect as motor depressants, thus preventing the convulsions. We are studying, as clinical material becomes available, the question as to whether these drugs may have some effect in raising the blood sugar in severe hyperinsulinism. The bromides are not advised in the treatment of hyperinsulinism, even when it is associated with epilepsy, except as a temporary measure. The bromism that follows the use of the bromides when used over a long period of time may be more harmful to the epileptic patient with hyperinsulinism than the convulsions. Phenobarbital in $1\frac{1}{2}$ grain (0.1 gm.) doses night and morning and in the most severe cases after the noon meal is the least harmful drug now known that will control the epileptic convulsions, and it is helpful in cases of severe hyperinsulinism in patients who cannot, or will not, follow a prescribed diet. Phenobarbital may be used in conjunction with dietary management in cases that are difficult to control.

Belladonna Having in view the possibility that belladonna might inhibit the secretory activity of the islet cells, I have used it in my mild cases of hyperinsulinism for several years, at times with seemingly good results.

Evans and his associates report the discovery of a diabetogenic hormone from the anterior pituitary, which will raise blood sugar. As yet this hormone has not been separated from the growth, and perhaps other, hormones, but there seems reason to hope that a purified product of the diabetogenic hormone will be available for use in hyperinsulinism in the near future.

Suprarenal Products Adrenalin (1 c.c. of 1-1000 solution) given hypodermatically will raise blood sugar, and in hypoglycemic coma may restore consciousness in a few minutes, but its effects are temporary and it is not of value in hyperinsulinism except in the attacks. Adrenalin has no effect when given orally, and it is questionable if any of the preparations

of suprarenal medullary substance are of value if given by mouth. Nielsen and Eggleston, however, credited a whole gland product of the suprarenals with a part of their successful treatment of three cases of epileptiform convulsions due to "dysinsulinism."

Ephedrine Ephedrine has been used successfully in the treatment of narcolepsy. Ephedrine mobilizes glycogen and, combined with diet and rest, may maintain the blood sugar level at a point high enough to prevent hypoglycemic symptoms. Ephedrine was used with doubtful results in two of our cases of epilepsy with hyperinsulinism.

Thyroid Extract Since hypothyroidism is sometimes associated with hyperinsulinism, thyroid extracts would seem to be indicated in the cases in which the basal metabolic rate is low. Tedstrom, and Evans and McDonough used thyroid extracts with benefit in the treatment of some of their cases of hyperinsulinism with low basal metabolic rate.

Insulin John reports having used insulin with excellent results in the treatment of hyperinsulinism. He is of the opinion that if exogenous insulin is given hypodermatically after meals before the postprandial blood sugar rise stimulates the secretion of insulin, the amount of endogenous insulin will be sufficiently reduced so that the hyperinsulinism patient will not become hypoglycemic several hours after meals. John gives from 10 to 20 units of insulin after meals and presents blood sugar records before and after the insulin was used, which seem to justify his conclusions. I have used insulin in two cases of hyperinsulinism with apparently good clinical results, though blood sugar studies were not made to prove that the blood sugar levels were higher after the use of insulin.

Deep Roentgen-Ray Therapy Barrow has used deep roentgen-ray therapy in the treatment of hyperinsulinism with reported good results. He believes that the irradiation over the pancreas may reduce the secretion of insulin just as it sometimes ameliorates the symptoms in hyperpituitarism with or without adenomas, presumably by decreasing hypophyseal secretion. In view of possible dangerous secondary irradiation of the liver, stomach, duodenum and other neighboring organs, this therapeutic method should be used with great caution in attempting to decrease insulin secretion. Sippe and Bostock quote Terbruggen and Heinlein as having "produced a lethal hypoglycemia in rabbits by irradiation of the pancreas." The external secretory portion of the organ, involved in producing trypsin, amylase and steapsin showed degenerative changes, whereas the islands of Langerhans were well preserved or even hypertrophic. Mosenthal also mentions irradiation of the pancreas as having caused hypoglycemia.

SURGERY IN HYPERINSULINISM

While the mild and moderately severe, and many of the very severe cases of hyperinsulinism can be relieved by dietary management, as certainly as diabetes mellitus can be controlled by diet and the use of insulin, in an oc-

casual case surgery offers the only hope of relief. The question then arises: When is surgery indicated in hyperinsulinism?

It should be stated emphatically that in no case of hyperinsulinism should surgery be resorted to until the patient has given a full trial to properly directed dietary management. Haphazard dieting in hyperinsulinism gives as unsatisfactory results as unscientific methods in the management of diabetes mellitus, so that the patient with hyperinsulinism has not had the best chance to control his disease unless he has been kept, for a few weeks at least, on a weighed and measured diet calculated and prescribed to suit his individual needs. If the hyperinsulinism patient cannot control his symptoms by properly directed dieting then surgery should be considered.

It is an interesting fact that of the 40, or more, operations on the pancreas for hyperinsulinism all but two have been performed by surgeons in the United States and Canada. There has not been a death reported from pancreatic operations performed in the United States, though I have heard of two deaths which resulted from operation that have not been reported. The only two operations on the pancreas for the relief of hyperinsulinism that have been reported, besides the American cases, were performed in Russia, both died from the operations. In one of these, a large adenoma of the pancreas, the growth had reached the stage where it was inoperable.

Criteria for Exploratory Operations An exploratory operation for the relief of hyperinsulinism should be considered

- 1 In the acute fulminating cases which develop rapidly and in which hypoglycemic attacks with convulsions and unconsciousness cannot be controlled by intravenous dextrose therapy, and in which death seems imminent.

- 2 In the severe chronic cases that cannot be controlled by properly directed dietary management in a few weeks.

- 3 In cases with severe neuro-psychiatric symptoms of long standing in which on account of economic or social or psychic handicaps the diet cannot be carried out properly, or long enough to permanently benefit the patient.

Surgery of the pancreas is contraindicated in primary disease, or hypofunction, of the anterior pituitary, the thyroid, or the adrenals, resulting in relative, or actual, hyperinsulinism, for the obvious reason that such operations could not remove the cause of the hypoglycemic symptoms. Likewise no benefit could be expected from surgery in hypoglycemia resulting from acute yellow atrophy of the liver, massive carcinoma of the liver, or the hepatic lesions that follow acute poisoning from hepatotoxins such as arsenophenamine, phenylhydrazine and the toxic varieties of mushrooms.

The Diagnosis and Treatment of Insulomas If it were possible to diagnose an islet cell adenoma or carcinoma before operation there would be no need for trying the patient on a diet, because in such cases surgery will give almost certain relief unless delayed until the neoplasm has advanced to the stage when metastases make the case an inoperable one. One of the most brilliant chapters in American surgery will be written when the results of operations on the pancreas for islet cell tumors have been recorded.

Unfortunately no one as yet has established the criteria necessary for diagnosing insulomas. Gammon and Tennyson summarize what is known regarding the differentiation between hyperinsulinism resulting from the neoplasms of the islands of Langerhans and the manifestations from functional insulogenic hypoglycemia, as follows: "All that can be said is that there is perhaps a tendency for the disease (hyperinsulinism) to be more rapid in its development, more severe in its manifestations, more erratic in behavior and more likely to cause death when tumor is present than in functional hypertrophy of the islands."

If an exploratory operation on a patient suffering from hyperinsulinism reveals an adenoma, or carcinoma, of the body or tail of the pancreas it should be removed, if possible. In one of Evarts Graham's series an islet adenoma the size of a baseball was removed from a psychotic patient with a clinical cure for two years, without any present indication of recurrence. If there are metastases in the liver and extensive involvement of the surrounding structures the case is inoperable.

In making an exploration for an adenoma of the pancreas it should be remembered that some of those found have been quite small, yet their removal completely cured the patients of hypoglycemic symptoms. Smith and Seibel found at autopsy an adenoma in the head of the pancreas less than 1 cm. in diameter, yet the patient died in hypoglycemic coma. It therefore should be remembered that even an exploratory operation may not reveal the adenoma that is causing severe hypoglycemic symptoms.

It should not be forgotten that though adenomas of the islands of Langerhans are usually single, two or more may be found in the same patient, and the removal of one may not relieve the patient of his symptoms. Evarts Graham in one case operated on a patient who had severe hypoglycemic symptoms and he removed an adenoma from the anterior surface of the body of the pancreas. The symptoms continued unabated. Later the second operation by Graham revealed another adenoma on the posterior surface of the body of the pancreas. The removal of the second tumor relieved the symptoms.

Resections of the Pancreas in Hyperinsulinism If an exploratory laparotomy on a patient suffering from hyperinsulinism does not reveal an adenoma or other operative lesions, but a normal appearing pancreas, should a resection be performed? As yet there are no criteria for performing resections of the pancreas in hyperinsulinism. Each case will have to be considered from its various aspects before deciding to resect a major part of the pancreas, or to close up the abdomen and give the patient another chance at dieting.

A brief review of some of the reported cases may provide data that should be helpful to the surgeon in making his decision in such a case.

The first resection of the pancreas for hyperinsulinism was performed in 1928 by Finney and Finney, who removed about three-fourths of the pancreas from a psychotic patient referred to them by Barker and Sprunt.

There was definite improvement, but not complete relief, though the blood sugar levels were higher following the operation. Six years later this patient committed suicide.

The next resection of the pancreas for hyperinsulinism was performed by Holman, with temporary relief of symptoms. This case was subsequently explored by Judd, who resected another portion of the pancreas with some relief, but the symptoms recurred.

Experience with Eight Cases of Surgical Hyperinsulinism I have advised surgical intervention in seven cases of hyperinsulinism. In three cases resections of from one-half to five-sixths of islet bearing tissue of the pancreas resulted in clinical cures. In two cases of epilepsy associated with hypoglycemia resection was followed by slight improvement, and in one case in which there was a history of probable dyspituitarism resection of five-sixths of the pancreas failed to control the epileptic attacks or the hypoglycemia. In the seventh case the abdomen was closed without resection of the pancreas after an exploratory laparotomy which revealed a normal appearing pancreas. This patient since the operation has adhered more rigidly to his diet and has shown a lessened frequency of his attacks of convulsions. The eighth case in which I advised operation was a patient of Dr J. E. Beck and Dr G. O. Segrist of Mobile. They had made a diagnosis of hyperinsulinism from very low blood sugar readings in a man who had been incapacitated for work for a year or more because of recurring periods of unconsciousness. The patient was violently psychotic at times. On account of the severity of the symptoms a tumor was suspected and I advised that the patient be sent to Dr. Evarts Graham of St. Louis, who operated, removing a large islet tumor. The patient made a complete recovery. He has had no symptoms in two years and is working regularly.

CONCLUSIONS

- 1 Hyperinsulinism, or spontaneous hypoglycemia, is a frequent and widespread disease, numerous cases having been reported by discriminating clinicians in many countries.

- 2 The manifestations of hyperinsulinism are protean, and identical with the symptoms that have been reported from overdoses of insulin in the treatment of diabetes mellitus.

- 3 The anamnesis is important in making the diagnosis of hyperinsulinism in the mild cases. Usually, there is a history of attacks of weakness, nervousness, trembling and sweating before breakfast, one or two hours before noon and evening meals, before retiring and often during the night. The attacks are relieved by taking food. In the more severe cases in addition to the mild symptoms, there is a history of recurring attacks of unconsciousness and convulsions, or hysteria. Neuropsychiatric, gastrointestinal and cardiac symptoms may be pronounced.

4 Low blood sugar readings, before breakfast, one or two hours before meals and in attacks, and the occurrence of a hypoglycemic phase in dextrose tolerance tests, are necessary for proof that the symptoms are due to spontaneous hypoglycemia. Dextrose tolerance tests should be carried out for six full hours before excluding the diagnosis of hyperinsulinism. The symptoms may, or may not be, reproduced in the hypoglycemic phase of dextrose tolerance tests.

5 The secretory interrelations of the pituitary, thyroid and adrenal glands with the insular apparatus of the pancreas should be considered carefully before making a diagnosis of uncomplicated hyperinsulinism. Likewise, hypoglycemia from deficient glycogenesis should be excluded before making a diagnosis of hyperinsulinism.

6 The great majority of cases may be relieved by a moderately low carbohydrate, high fat diet with frequent feedings between meals, and at night if there are nocturnal symptoms. The diet should be prescribed to meet the individual needs of the patient under treatment.

7 Surgery offers relief in cases that cannot be relieved by properly directed and carefully carried out dieting over a period of a few weeks or months. The removal of insulomas, either adenomas or carcinomas, of the islands of Langerhans has resulted in clinical cures. Resection of the pancreas relieved the symptoms in about 50 per cent of reported cases.

8 Two fatal cases of islet cell carcinomas have been reported which were inoperable because of the size of the tumors and the presence of liver metastases. It, therefore, is important to make the diagnosis of hyperinsulinism early before the neoplasm of the islands of Langerhans has progressed to the inoperable stage.

MASSIVE DOSES OF VITAMIN D IN THE TREATMENT OF PROLIFERATIVE ARTHRITIS ^{*}

By BERNARD L. WYATT, M D , F A C P , ROBERT ALAN HICKS, M D ,
and H E THOMPSON, M D , *Tucson, Arizona*

RECENT interest in the treatment of arthritis, by massive doses of vitamin D,¹ has been sufficiently great to warrant a clinical trial of this mode of therapy in a group of patients with the chronic proliferative (infectious) type. Past experience of disappointing results when such recommended therapeutic agents as gold and sulphur were used over an adequately long period under controlled clinical conditions had rendered us somewhat skeptical but it appeared worthwhile, however, to determine if vitamin D might constitute a valuable adjunct to a composite program of treatment in this group of diseases.

Thirty-eight patients having chronic infectious or proliferative arthritis and two patients in the same group, but with histories of earlier rheumatic fever, were selected. These patients had been under observation for at least six months and six complete clinical and laboratory check-ups had been made. It was possible thereby to contrast their progress before and after the administration of large doses of vitamin D. In evaluating any therapeutic agent in the treatment of arthritis, such a control is more valuable than is a study of parallel groups (one with and one without the test treatment). Comparison before and after institution of the use of a given therapeutic agent in well-studied patients is of greater value in our experience than the analysis of data from treated and non-treated groups.

The indications for the use of massive doses of vitamin D are considered to be the presence of proliferative arthritis and, inasmuch as the work was experimental, no special selection was employed among members of this group, other than that any patient was eliminated whose general condition was such that a severe reaction might be disastrous.

Later, it became evident that the presence of a very sensitive colon contraindicated the use of the vitamin in large quantities. In general it was found that the type of arthritic patient for whom vaccine is indicated, that is, a patient in whom desensitization seems to be the main problem, was decidedly not the type in which to use massive doses of vitamin D. When a high sedimentation and low agglutination titers were taken to indicate the desirability of the employment of streptococcus vaccine, then the use of massive doses of vitamin D seemed inadvisable.

The method employed in this work had as its first step the evaluation of clinical progress and laboratory changes in each patient up to the time of administration of vitamin D. After this base line in degree of progress for

^{*}Received for publication June 22, 1936

From The Wyatt Clinic and Research Laboratories, Tucson, Arizona

six months was established massive doses of vitamin D with supplementary medication (vitamin B and calcium) were instituted and similar studies of the patient continued to see if more definite progress toward recovery would result

The dose employed was never increased over 300,000 units of vitamin D daily and the ordinary dose most often used was 200,000 units daily. Under no circumstances did we see reason to increase the dose to the enormously high levels that have been reported by some workers.

The sources of vitamin D were as follows: irradiated ergosterol in sesame oil supplied for experimental purposes by the National Institute of Nutrition, Los Angeles; viosterol and vitamin D in propylene glycol.

The supplementary medication employed consisted of a good source of vitamin B, such as wheat germ or brewer's yeast and calcium supplied in the form of dicalcium phosphate and milk.

The additional treatment of these patients consisted of a definite regimen used in this Clinic. This treatment may be briefly summarized: Adequate rest, physiotherapy, heliotherapy, dietotherapy, treatment or early removal of foci, blood transfusions, orthopedic measures and intravenous bacterial antigen. Obviously, under such a program, there were individual variations. However, these were minimized as much as possible.

The results of treatment in 40 patients were evaluated in two ways. First, clinical improvement, such as diminution in joint pain, swelling and stiffness, increase in general strength, appetite and weight, was noted; second, laboratory changes were studied once a month and included the determination of the sedimentation rate, agglutination reactions for streptococci, morphological blood picture and the level of calcium and phosphorus content of the serum.

The percentage of clinical improvement noted was considered definite and clear-cut in 20 per cent, i.e., in eight patients in this series we could detect a definite progressive increase in appetite, weight, general feeling of strength and a decrease in joint swelling, pain and stiffness. Similarly, in eight patients, or 20 per cent of the total series, it was necessary to abandon the treatment entirely on account of unfavorable reactions.

One patient complained of violent persistent nausea for four days, intense headache and profuse sweating. In another patient, severe diarrhea was the only evidence of a reaction, but necessitated the withdrawal of the therapeutic agent. Reactions in the remaining six were vague conditions developing in the first week of treatment characterized by beginning loss of appetite, drowsiness, slight headache often present on awaking in the morning but worse with the advance of day. However, the symptoms in the latter disappeared in about 48 hours following the stopping of vitamin D.

The remaining 60 per cent, or 24 patients out of the 40 treated, during the period of our observation, showed no definite benefits that could be attributed to vitamin D therapy.

In more than half of the patients, therefore, vitamin D concentrates did not seem to hasten recovery. It should be borne in mind in this connection, however, that treatment problems in chronic proliferative arthritis are so complicated and so manifold in their aspects that we are hesitant to say at the present time that some of these 24 patients, during the next few months, may not show some improvement due in part to their vitamin D therapy.

From a study of over 500 cases the base line for the laboratory changes in patients under treatment in this Clinic is well established and in this series studied with the use of vitamin D no significant departure was observed. For example, the morphological blood picture did not alter in these patients more rapidly or more distinctly in general than it does in other patients being treated without vitamin D. Calcium and phosphorus determinations exhibited only minimal changes, the average increase in calcium content of the serum being 0.75 to 0.95 mg. All determinations were within normal limits. There was no significant change in the calcium phosphorus ratio noted.

These results may be briefly summarized as follows. On a composite program of therapy 40 patients with chronic proliferative arthritis received massive doses of vitamin D. Out of this group eight were definitely improved clinically, eight exhibited more or less severe reactions, the remainder exhibited no improvement attributable to the medication. The laboratory tests employed to follow the progress of these cases did not show any significant changes.

CASE REPORTS

ARTHRITIS PSORIATICA, REPORT OF A CASE *

By HERMAN SHLIONSKY, M D, and FRANCIS G BIAKE, M D, F A C P,
New Haven, Connecticut

THIS case of psoriasis and destructive bone and joint changes is reported because the pathological process of the bones and joints is of an unusual character

CASE REPORT

M G, housewife, 57, native born, of Irish extraction, was admitted to the Psychiatric Clinic of the Institute of Human Relations, December 26, 1934, with a history of psoriasis and of multiple joint involvement leading to mutilating deformities of the hands and feet—the skin and joint conditions having both begun about 20 years ago. The reason for admission to the Psychiatric Clinic was that the patient had a psychosis of three months' duration characterized by depression, agitation, suicidal tendencies, somatic and self-accusatory delusions, and auditory and visual hallucinations, this mental condition was diagnosed by the staff as one of agitated depression (involuntional melancholia). After about three months she was transferred to the Norwich State Hospital, the mental condition unchanged. Prior to the onset of the psychosis the patient had been considered a normal individual and had made a satisfactory adjustment to the environment in the face of a chronic and serious physical handicap.

Family History The paternal grandmother died at the age of 92, of "arthritis." Beyond the fact that she had been unable to walk for 10 years prior to her death, no details were obtained concerning the nature of the supposed arthritis. The family history shows no other instances of rheumatic disease and is non-contributory in other respects.

Past History The birth and early development are considered to have been normal. The patient was married at the age of 26 (1903) and widowed 12 years later. There were three pregnancies (1904, 1908, and 1911), all going to term. The menopause occurred about 1924 and was associated with the appearance of black spots before the eyes. Her general health up to the age of 37 (when the present illness began) was good, but there was some tendency to obesity. The past infectious illnesses include grippe (two attacks), and possibly measles and chicken pox. Although the patient is said to have suffered from "valvular disease" of the heart since about the time of onset of the present (physical) illness, there have been no definite symptoms of heart failure. A review of the organ systems discloses the following: chronic constipation, some tendency to gaseous eructations and "sour mouth", occasional mild swelling of the feet (probably postural or due to local lesions rather than cardiac), occasional frontal headaches, vague history of precordial pain about three years ago. There is no history of tuberculosis, syphilis, or gonorrhea.

Present Illness About 1913 (age approximately 37) the patient developed a psoriatic rash and at about the same time some form of multiple joint involvement

* Received for publication June 6, 1936
From the Departments of Psychiatry and Internal Medicine, Yale University, School of Medicine

that suggested at the time a questionable diagnosis of rheumatic fever. She remained in bed for about a year, during which time all her teeth gradually dropped out. The rash was early generalized, remained permanent and was refractive to treatment, however, it usually receded during the summer months of July and August. The joint involvement likewise persisted permanently, and it included the elbows, knees, and the articulations of the hands and feet. Deformities of the hands and feet appeared early in the course of the disease and progressed steadily, reaching in 1929 practically the extreme stage noted at the time of admission. Apart from the first year of illness, the patient was up and about, and active in caring for a large household until incapacitated by the psychosis.

General Physical Examination The patient was short, of pyknic habitus and despite the history of loss of weight, appeared well developed and nourished. Facial hirsuties and a tendency to prognathism were apparent, otherwise there were no signs related to possible endocrine stigmatization. A slight degree of exophthalmos (constitutional) was noted. The irides were discolored (old iritis), both eyes showed posterior synechiae, and the left eye was highly myopic with a posterior crescent. All the teeth were missing and the alveolar processes absorbed. The breasts were atrophic. The heart did not appear enlarged on percussion, the sounds were regular and of good quality, with accentuation of the second aortic sound and with a systolic murmur at the apical region. The radial artery was compressed with difficulty, and the blood pressure was 174 systolic and 100 diastolic. A second degree rectocele and external hemorrhoids were present. There was no evidence of trophic disturbances of the skin in the extremities and the dorsalis pedis was easily palpated in each foot. The neurological examination was negative; there was no motor weakness except that due to the bone and joint involvement, the deep reflexes were active and equal, and sensory changes in the extremities were not elicited.

Examination of the Skin There was a generalized psoriatic eruption with free coalescence of lesions and the production of many gyrate and polycyclic forms. The nails of the hands and feet were thickened, crusted and lined with prominent transverse grooves. The palms of the hands alone were spared in the generalized involvement.

Orthopedic Examination There was evidence of multiple joint involvement with the most striking changes in the distal portions of the extremities. The spine showed a moderate degree of kyphosis in the dorsal region and its motility was generally reduced.

Both shoulder joints appeared to be of normal size and permitted free movement except that on the right the patient could not raise the arm above the horizontal level and had to flex the elbow to reach overhead. The right elbow joint (figure 1) was enlarged and permitted extension only to about 120 degrees, the size of the left elbow joint and its movements were not remarkable. Pronation-supination of the forearm was considerably limited on the right but quite free on the left. There was complete ankylosis of the right wrist and partial of the left.

Both hands (figure 1) were deformed and shrunk to at least half their normal size, giving one the first impression of a congenital anomaly. The skin over the dorsum of the hand, particularly over the fingers, was loose, with the formation of transverse grooves most marked at the metacarpal-phalangeal joints. The interphalangeal joints showed complete ankylosis while the metacarpal-phalangeal articulations were transformed into ball and socket joints. There was practically no power in the fingers, the patient holding objects by pressure at the palms.

Motion was free and power good at the hip joints, which presented no superficial signs of abnormality. The right knee was slightly increased in size but permitted free motion, the left knee gave no positive findings. Movements of flexion-extension at both ankle joints were limited to within a range of about 10 degrees.

At both sub-astragaloid joints the movements of inversion-eversion were practically nil. The feet (figure 2) showed changes corresponding to those in the hands: considerable shortening at the metatarsal regions, marked shrinkage and deformity of the toes, complete ankylosis of the interphalangeal joints, transformation of the metatarsal-phalangeal joints into ball and socket articulations, and practically com-

FIG. 1

plete loss of power in movements of the toes. As a result of the deformities in the feet, the patient walked on the outside of the left foot and mostly on the heel of the right with a shuffling gait.

FIG 2

Laboratory Data Blood examination showed 3,700,000 red blood cells per cubic millimeter with 70 per cent hemoglobin (Sahli), and 7,500 white blood cells with a normal differential count.

Routine urine examination was negative except for the presence of 2 to 4 finely granular casts per low power field.

The blood Kahn test was negative. Examination of the spinal fluid gave normal results with regard to hydrodynamics, chemistry, cell count, and the Wassermann and colloidal gold tests.

Blood chemistry (January 14, 1934) showed the following

Serum total proteins 7.61 per cent
" albumin 4.11 per cent
" globulin 3.50 per cent
" calcium 8.74 per cent
" phosphorus 4.01 per cent

A hemolytic streptococcus agglutination test (November 24, 1935*) in which the patient's serum in dilutions ranging from 1:10 to 1:1280 was tested with a strain of hemolytic streptococci known to be agglutinated by arthritic serum in high dilution, was entirely negative.

FIG 3

Radiographic Report (Dr H. M. Wilson, Yale University School of Medicine) Films of both hands (figures 3 and 4) and the left foot (figures 5 and 6) made in this laboratory, and of the shoulders, knees and elbows made in another laboratory (Norwich State Hospital†) reveal the most striking changes in the extreme distal ends of the extremities with similar but milder changes in the more proximal portions of the extremities. There is some osteoporosis of all the bones, characterized by concentric atrophy with evidence of thinning of the cortical compact bone and associated with some coarsening of the trabeculations, which reaches an extreme degree in the

* This test was carried out in the bacteriological laboratory of the Hospital for Joint Diseases, New York City, through the courtesy of Dr H. L. Jaffe.

† The cooperation of Dr C. Waterman, Superintendent of the Norwich State Hospital, Conn., made possible the follow-up study of the patient and access to these films.

phalanges of the left hand The tendency to osteoporosis becomes accentuated about the joints, especially in the distal ends of the extremities, where massive absorption of bony substance occurs

There are osteochondritic changes in the shoulder joints most marked in the left shoulder about the humeral head characterized by irregular and alternating areas

FIG 4

of rarefaction and condensation The right shoulder girdle shows a tapered narrowing of the outer end of the clavicle with loss of substance from its distal extremity The acromioclavicular joint space is widened There is condensation and irregularity of the acromion process

Moderate proliferative changes are noted in both knee joints, particularly about the superior aspects of the patellae This change appears to be associated with localized decalcification along the superior border at the attachment of the quadriceps tendon

The elbow joints show narrowed joint spaces with an irregular osteoporosis of the olecranon process giving it a spongy appearance There appears to be flattening and possibly telescoping of the radial head on the right

At the left hand the distal $2\frac{1}{2}$ centimeters of the left ulna are tapered to a point, with sclerosis and obliteration of the medullary cavity, the lower 3 centimeters of the left radius likewise show sclerosis and obliteration of the medullary cavity but without the tapered narrowing, and the articular surface is deformed The proximal carpal bones with the exception of the pisiform are missing while the distal carpal bones are fused into a contracted and flattened mass The carpo-metacarpal joint spaces are obliterated and the metacarpals show the same tapered narrowing with

loss of the heads which characterized the change in the left ulna. The proximal portions of the proximal phalanges show essentially the same changes as do the metacarpals. The distal portions of the proximal phalanges and the remaining phalanges show extreme osteoporosis with cortical outlines a fraction of a millimeter in width. As a result of the loss of bony substance of the lower ends of the radius

NEW HAVEN HOSPITAL
LEFT A 16044
71 36 AMH

FIG 5

and ulna, and of the carpals, metacarpals and phalanges, there is extreme shortening of the hand with the soft tissues creased and redundant. An essentially similar process involves the right hand although the changes are somewhat more pronounced in the hand and less marked in the carpus and radio-carpal joint than noted on the left.

The tarsals, metatarsals and phalanges of the left foot show a process similar to that involving the corresponding bones of the hand.

COMMENT

The clinical association of psoriasis and joint involvement, first comprehensively studied by Bourdillon (1888),¹ has been frequently described in the recent literature. Although practically every type of chronic joint disease has

FIG 6

been reported as occurring with psoriasis, one variety has received special emphasis with regard to its relationship to the skin condition. This form of arthritic disease is characterized by chronic usually multiple joint involvement often leading to early deformity and to gradual destruction of the joints. Some authors (Adrian,² Nobl and Remenovskiy,³ Zellner⁴), on the basis of certain clinical and roentgenological criteria, consider this type of arthritic disease peculiar to psori-

asis and would restrict the term "arthritis psoriatica" ("psoriasis arthropathica") to cases of psoriasis with this form of joint involvement. Others (Bauer and Vogl⁵), on the other hand, although admitting the existence of a probable etiological relationship between psoriasis and joint disease, deny the specificity of the articular changes of arthritis psoriatica and place them in the category of ordinary primary chronic (infectious) polyarthritis.

Whatever its nosological status, the group of cases included under the heading of arthritis psoriatica are characterized, as indicated above, by the frequent tendency to marked destructive changes of the joints. In some cases the destructive process also involves to a considerable degree the bone in the distal end of the extremities, resulting in a picture that would appear to be a mild form of the involvement characteristic of our case. Thus cases with atrophy and destruction of the phalanges of the hands and feet to the extent that several phalanges have been almost entirely absorbed are not uncommon (Adrian,² Wollenberg,⁶ Balzer and Burnier,⁷ Strom⁸, Schumacher and Lauter,⁹ Nobl and Remenovsky,³ Scholl,¹⁰ Rodnei¹¹). Extension of the destructive process to the metacarpals and carpals has also been observed if less frequently (Falk,¹ Zellner⁴). Furthermore in one case with metacarpal involvement (Zellner⁴) the distal ends of these bones have disappeared leaving tapering fragments of bone as seen in our case.

The involvement of the bone in the proximal portions of the extremities has not been described as frequently in arthritis psoriatica, but in a case reported by Lotze¹³ an area of rarefaction and condensation in the head of the humerus, and an area of absorption in the patella associated with proliferative changes in the knee joints resemble the lesions of the corresponding areas in our case.

In reviewing the literature we were able to find the description of only one case of psoriasis and bone and joint involvement which we would consider comparable to ours with regard to severity as well as to type of bone and joint change—that presented by Bauer and Vogl.⁵ In comparing the two cases one notes similar clinical courses and the same type of involvement of the hands and feet as characterized by the extensive loss of bony substance and the tapered narrowing of bony fragments. Bauer and Vogl consider their case an instance of ordinary primary chronic (infectious) polyarthritis, in keeping with their view referred to above, that cases of arthritis psoriatica fall into that category.

The bone and joint changes of our case also suggest a comparison with those described in a condition independent of psoriasis, namely, a rare form of arthritis, "main en lorgnette," only two cases of which have been reported in the literature—the original by Marie and Lévi,¹⁴ and the second by Weigeldt.¹⁵ These cases resemble ours in showing the following features: chronic progressive multiple joint involvement with extreme changes in the distal ends of the extremities, massive absorption of bone in the hands with tendency to tapered narrowing of bony fragments, and formation of transverse folds in the skin of the fingers (due to the disproportionate shrinkage of the bones and the soft tissues). This peculiar folding of the skin of the fingers, suggesting the appearance of an opera glass, prompted Marie and Lévi to select the descriptive name of "main en lorgnette." The two cases designated by this name are considered by their respective authors as special instances of chronic infectious polyarthritis.

The fact that a bone and joint process similar to that in our case appears in a condition not associated with psoriasis would argue against the assumption that

the type of bone and joint involvement characteristic of our case is peculiar to the skin condition, even if the two may be etiologically related

CONGENITAL DILATATION OF THE PULMONARY ARTERIES REVEALED BY ROENTGENKYMOGRAPHY *

By SYDNEY E JOHNSON, M D, F A C P, *Louisville, Kentucky*

ROENTGENKYMOGRAPHY is so new an addition to the diagnostic procedures of roentgenology that few physicians in general practice are aware of its value and diagnostic indications. The writer is of the opinion that the method has a wide field of usefulness and that it will come into general use in radiological practice as soon as its various applications are more generally known.

Roentgenkymography differs from other roentgenographic methods in that its single function is to record movement (and negatively, the absence of movement in organs or parts of the body that normally have movement). With this method it is possible to make a permanent graphic record of the movement of any part or organ of the body that can be depicted in the ordinary roentgenogram. Often the movement curves are susceptible of quantitative and qualitative analysis of great accuracy. Ventricular, auricular, and arterial movement curves are characteristic and show characteristic modifications in certain cardiovascular diseases. Movements of the diaphragm, gastrointestinal canal, deglutition, articulations, chest wall, etc., may be studied in the fixed curves of

* Received for publication April 23, 1936

the kymogram, or the recorded cycle of movement may be reproduced visually in a special viewing machine, the kymetoscope which produces the illusion of continuous motion

The mechanical details and groundwork of roentgenkymography have been covered by Stumpf,¹ and Hirsch.² The next logical step is the reporting of specific cases in which the method has elucidated otherwise obscure points in the diagnostic picture. To justify itself, the method must give information that is not as readily obtainable by other methods. A first case of this kind was reported by the author in August 1935.³ The case reported herewith furnishes another illustration of the value of roentgenkymography in a type of case that usually presents diagnostic difficulties, congenital heart disease

FIG 1

CASE REPORT

The subject of this report is a white male school teacher, aged 38 years. He has no complaint and was unaware of his abnormality until he applied for life insurance in December 1934. His mother died in 1909, probably of tuberculosis. Aside from this, the family history is negative. He has been in good health prac-

FIG 2

tically all of his life, but says that when he was a child his parents were told that he had an abnormal heart. He led a life of normal activity. There is no history of cough or expectoration. The man shows average build, development and nutrition. Pulse rate 84, blood pressure 104 systolic and 78 diastolic, respiratory rate 20, normal

temperature. He served in the World War and was discharged without disability. His tonsils were removed in 1929, and the appendix in 1930. In 1927 he had influenza and, due to a rather prolonged convalescence, visited a large clinic for general medical examination. He was told that he had mitral stenosis and would have about 20 per cent disability.

In 1934 an insurance company's medical examiner elicited percussion findings which led him to suspect old fibrotic tuberculosis and the applicant was referred to the Waverly Hills Tuberculosis Clinic. A chest film made at the Clinic (figure 1) shows large, sharply defined masses projecting into both lung fields, and pronounced enlargement of the upper left cardiac border. The lungs are singularly clear. No evidence of tuberculosis was found. The differential diagnosis lay between Hodgkin's disease or some other type of neoplasm and anomalies of the heart and great vessels. A faint presystolic murmur was the only abnormal heart sound elicited. There was no clubbing of the fingers. No subjective symptoms were present.

Because of the unusual roentgenographic findings, the patient was referred to the writer for roentgenkymographic examination with the idea of determining whether the masses in the thorax were of vascular origin or solid tumors. This question is clearly answered by the kymogram (figure 2). Not only do the masses show expansile pulsation, but the curves are unmistakably arterial.

In the light of these findings and of the history we believe that the evidence is sufficient to justify a diagnosis of congenital dilatation of the pulmonary arterial trunks and probably the ductus arteriosus and conus arteriosus. Conventional teaching would lead us to anticipate more in the way of physical signs and subjective symptoms in cases of this type. It seems probable that roentgenkymography will teach us some hitherto unknown facts about these cases, especially in relation to clinical manifestations.

RAYNAUD'S DISEASE IN MAN

By A. M. RECHTMAN, M.D., F.A.C.S., *Philadelphia, Pennsylvania*

RAYNAUD'S disease in man is not common. Only seven cases were seen at the Mayo Clinic¹ which fulfilled the criteria Allen and Brown considered necessary for a diagnosis. It is generally conceded that the majority of male patients in whom a diagnosis of Raynaud's disease has been made have in reality been cases of thromboangitis obliterans.

Raynaud described four features whose presence he considered necessary for a diagnosis of the disease bearing his name:

- 1 Episodes of change in color, of the vasospastic type, excited by cold or emotion.

* Received for publication January 2, 1935.

- 2 Bilaterality
- 3 Presence of normal pulsations in the palpable arteries
- 4 Absence of gangrene or its limitation to minimal grades of cutaneous gangrene

To these Allen and Brown¹ added two further criteria

- 5 The absence of any disease which might be causal, such as organic disease of the nervous system
- 6 Symptoms of two years' or longer duration

The author feels that the following further requirements should be insisted upon in the interest of more accurate differential diagnosis

- 7 Obliterative vascular disease should be excluded, not only by the absence of gangrene (or its limitation to minimal cutaneous areas), but also by the determination of normal arterial pulsations by Pachon oscillometric readings, and by the demonstration of normal reflex temperature variations in the affected limbs with the thermocouple
- 8 The characteristic changes in the capillaries of the nailfold, described by Brown,^{2,3} should be shown to be present

Two male cases of peripheral vascular disturbance are presented which conform to the above criteria for Raynaud's disease. Both were studied on the author's orthopedic service at the Jewish Hospital in Philadelphia

CASE REPORTS

Case 1 M K, male, aged 36. The patient's symptoms started six (6) * years before his first visit on January 24, 1932. When his hands were exposed to cold weather, the second, third, fourth and fifth fingers became numb and "absolutely white" (1) The two distal phalanges of the second and third fingers, the distal phalanx of the fourth finger and the tip of the fifth finger of the right hand were involved. The numbness would abate when the patient was in a warm room for 30 minutes, or within five minutes if the hand was placed in hot water, when it then became red and dusky. Hyperesthesia as a pin- and needle-like sensation and a "scratchy, irritating, queer feeling" persisted until the normal appearance was restored. Placing the hands in cold water for five minutes caused the color changes. He learned to protect his hands against the cold which caused the syndrome and to warm them to hasten recovery.

On examination, January 30, 1932, at a room temperature of 70° F the color of both hands (2) was red and dusky, to above the wrists. The left or subjectively uninvolved side was more dusky. The face had the same color changes, but not the remainder of the body. Elevating the hands lessened the color, but not to the normal. The pulsations (3) were equal on both sides and of good volume in all the vessels of the upper extremities. The radial, and then the ulnar arteries were compressed, but no occlusion of the smaller vessels was demonstrated.

Pachon oscillometric (7) studies of the extremities showed the following readings

Right Arm	4	Left Arm	5
" Forearm	8	" Forearm	6
" Foot	2	" Foot	1
" Ankle	5	" Ankle	5
" Calf	10	" Calf	10

* The bold face numbers coincide with those of the criteria previously recorded as necessary for a diagnosis of Raynaud's disease

Thermocouple (7) readings (Coller and Maddock) were taken. The patient was exposed for an hour, the room temperature was 70 degrees. The average temperature on the right side was 28 degrees C and on the left side 28.5 degrees C. The body was wrapped in a rubber sheet, surrounded by blankets for an hour and the skin temperature readings were again determined. The right side averaged 32 degrees C and the left side 32.4 degrees C.

The systolic blood pressure was 106. There were no evidences of trophic changes in the nails (4) or of gangrene. The family history was negative for circulatory disturbances.

Roentgen-ray examination (5) showed no evidence of a cervical rib or other cervical bony lesion to account for the disturbed circulatory condition. Examination of the capillaries (8) of the nailfold* showed the findings to be similar in the fingers of either side (2). The capillaries in the field were shorter and fewer than usual. The capillaries were tortuous and slightly more dilated than normal.

Discussion This case fulfilled seven and partially the eighth criteria for a proved diagnosis of Raynaud's disease. The bilaterality was but partially fulfilled. The color syndrome with pallor was present in the right hand only. When no attack was present, the color of both hands was a dusky red. The capillary nailfold study showed findings on either side, similar to those seen in patients with Raynaud's disease.

Case 2 L. R. W., male, aged 22, was referred by Dr. A. E. Ohiensis. History: The patient first noticed the condition four years before his examination on May 5, 1933. He said the second finger of the left hand was blanched (white) on change of weather. The color changes occurred in cold or warm weather on damp or mucky days, and they also occurred when he put his hands in cold water (1). He first had a numb and stiff feeling, the part became white and then changed to a slightly reddish hue and felt warmer than normal. This continued for about 10 minutes. The color variation occurred at times when he was very tired, or if he washed his hands briskly. Two years after the onset, the third and fourth fingers were similarly involved. The precipitating factors remained the same. At times both hands were affected (2). During six months previous to this examination the left hand was only occasionally involved and only in very cold weather. The right hand was usually involved.

The patient said he made a bid of 420 of spades in a pinochle game and needed eight points to win. Toward the end of the playing he noticed that the second, third and fifth fingers of the right hand were blanched and white. The fifth finger was but rarely involved and had been involved only for the preceding year. The fifth finger was involved about one time in 50 episodes of change of color as compared with the second and third fingers of the right hand. The second finger on the left hand was involved about one time in ten.

The more frequent involvement of the right hand may have been due to its greater use in shaking hands (4), i.e. by pressure, or by its use in holding objects, such as a glass of ice water. The right hand alone was involved when the patient was excited, as during a card game. The stimulation of exposure to cold, however, caused both hands to be affected.

Examination The color of the patient's hands (1) changed from time to time during the several examinations made. The finger nails were all of a dusky hue. At times the color was normal. The color of the hands, to above the wrists, was usually dusky than normal. The color appeared normal when the hands were warmed beneath a blanket for an hour. At such times only were the hands warm.

*I wish to express thanks to Drs. Mitchell Rubin and C. H. Church of the staff of the Children's Hospital, Philadelphia, for their aid in the capillary nailfold studies.

The patient complained of a tingling sensation when the fingers were blanched. This continued during the period of cherry redness which followed. Blanching occurred on pressure of the hands, exposure to cold, and after excitement. It lasted for a period of from ten minutes to an hour and was of longer duration on a cold day. Blanching and stiffness first occurred in the second and third fingers and then in the fifth finger of the right hand. The color of the fingers changed to a dusky or purplish blue as the blanching abated. There was a sensation of numbness but no pain and the color gradually became a beefy red and a tingling sensation occurred. The natural color then returned but was a deeper red than normal unless the hands were warm. The normal color was slow in returning but it could be hastened by the application of heat or by massaging the fingers.

A study of the pulses (3) on palpation showed them to be equal in force and volume and present in all the palpable vessels of the extremities. Compression of the radial and then the ulnar arteries in both hands showed a normal return of the blood flow. The blood pressure was 114/80 on the left side and 112/82 on the right. Pachon (7) oscillometric readings were

Right Wrist	2	Left Wrist	1
“ Forearm	5	“ Forearm	4½
“ Arm	5	“ Arm	4½
“ Foot	½	“ Foot	+
“ Ankle	1¼	“ Ankle	1½
“ Calf	7	“ Calf	6
“ Thigh	6½	“ Thigh	6

Thermocouple (7) readings (Coller and Maddock) before dilation, at a room temperature of 72° F, showed the right hand averaged 23° C, and the left hand 23.4° C. After the patient was wrapped in a rubber sheet and surrounded with blankets for an hour the average skin temperature of the finger tips was 31.6° C on the right side and 32.3° C on the left side. There was no evidence of trophic, (4) gangrenous or ulcerative changes. Roentgen-ray examination for cervical rib was negative. A study of the capillaries (8) in the nailfold showed fewer capillaries to the field. The flow of blood in the capillary loops was slowed or stopped. The capillaries were more tortuous and had bulbous tips.

Discussion This case fulfills all eight criteria herein recorded for a diagnosis of Raynaud's disease.

SUMMARY

Two cases of Raynaud's disease in male patients are reported fulfilling the four criteria of Raynaud, and the two of Allen and Brown. These cases also met the additional diagnostic requirements suggested by the author, namely, normal oscillometric readings, normal reflex temperature variations, and characteristic abnormalities of the nailfold capillaries, in the affected extremities.

EDITORIAL

THE GASTRITIS PROBLEM †

IN the past decade there has been a marked revival of interest in gastritis. This is largely attributable to the following factors: (1) the present vogue, especially on the continent of Europe, of performing gastric resection for benign gastric and duodenal ulcers, as well as for malignant lesions, thus permitting histopathologic study of fairly large portions of the freshly resected gastric tissue, (2) the more general use of the gastroscope, which has been greatly improved in recent years, (3) progress in the roentgenographic study of the mucosal relief. Accessory to these major factors are the following: specialized biochemical and cytologic studies of the gastric secretion as an aid to the diagnosis of gastritis, researches directed to the experimental production of the lesion, investigations as to the rôle gastritis plays in the genesis of ulcer, carcinoma, various forms of anemia, and postoperative sequelae, accretions to knowledge from gastrophotographic observations, speculations concerning the clinical significance of gastritis when associated with duodenal or gastric ulcer, and finally, the influence of an increasing literature on the subject in the form of articles, monographs and atlases.

The problem of most concern to physicians and surgeons, simply stated, is this: To what extent is gastritis or gastro-enteritis, especially in its chronic form, the underlying cause of those conditions diagnosed as pseudo-ulcer, nervous indigestion, gastrototoxic hemorrhage, duodenitis, gastrogenic diarrhea, achylia gastrica, pseudocholecystitis, and of those relatively infrequent cases presenting antral defects, which are usually labeled scirrhus carcinoma or syphilis but which do not present evidence of either on histologic examination of the resected tissue? The same problem applies to certain late postoperative sequelae. What diagnostic procedure is the most reliable? Granting the presence of gastritis, to what extent is that condition responsible for the underlying complaint in a given case?

With certain primary and secondary types of gastritis—acute, subacute, chronic phlegmonous, specific and perianastomotic—we have long been familiar. The acute and chronic forms of alcoholic gastritis, atrophic gastritis associated with pernicious anemia, and the phlegmonous form of gastritis have been particularly well known. The hypertrophic, subacute and chronic forms have been frequently found at necropsy to be associated with disease of the liver, heart, gall-bladder and certain metabolic and endocrine disorders. Syphilitic gastritis in its various forms has been encountered repeatedly. In more recent years we have become impressed with the frequency of occurrence of hypertrophic, erosive and ulcerative forms of subacute gastritis in association with obstructive lesions of the stomach and duodenum. Baker's recent histopathologic studies of the

* Submitted for publication July 30, 1936

gastric mucous membrane of patients undergoing gastric resection for malignant and benign lesions, with or without obstruction, also discloses the high frequency of occurrence of definite gastritis even in gastric mucous membrane remote from the lesion. This fact does not necessarily imply that gastritis was a precursor of the ulcer or cancer.

Of especial interest are those instances of primary gastritis encountered at operation and confirmed by histologic examination of excised or resected gastric tissue. In such cases the inflammatory process is sufficiently extensive to give rise to gross defects, usually antral in situation and recognizable by the ordinary roentgenologic technic. Such defects are indistinguishable from those produced by carcinoma in particular, by syphilis, by chronic hypertrophy of the pylorus, and by gastric ulcer when associated with antral spasm. From a symptomatic standpoint the cases can roughly be divided into three types according as to whether they simulate (1) cases of ulcer or cancer with irregular symptoms, (2) cases in which the symptoms closely simulate those of ulcer, and (3) cases characterized by pain, or simulating cholecystic disease.

From the symptomatic standpoint, the traditional conception of gastritis, of the subacute and chronic variety in particular, in contrast to the contemporary conception, is worthy of consideration. Past teaching and experience led to the belief that changes confined to the gastric mucosa did not necessarily give rise to any frank gastric phenomena, with the exception of occasional hemorrhage and possibly of vague epigastric discomfort, although such indirect symptoms as anemia and intestinal disturbances, especially diarrhea, frequently occurred. But such authorities as Faber, Schindler, Henning, Konjetzny, Katsch and others, on the basis of gastroscopic, surgical and pathologic findings maintain that a variety of symptoms common to gross lesions of the stomach may be engendered by the various forms of gastritis. While it is still true that extensive gastritis may be present without giving rise to any appreciable gastric disturbances, increasing experience justifies the pronouncement of the authorities just cited. Certainly, primary subacute and chronic, erosive and ulcerative forms of gastritis, in which the gastric content contains free hydrochloric acid, do give rise to symptoms highly suggestive of gastroduodenal ulcer or to massive hemorrhage, and the chronic hypertrophic anacid variety may engender less active symptoms suggestive of cancer, cholecystic disease, or functional gastric disorders as well as of ulcer.

Of all the procedures advanced for the diagnosis of gastritis, it is generally conceded that gastroscopy is the most reliable. Careful roentgenoscopic study of the mucosal relief is helpful at times. In Berg's opinion, characteristic of gastritis from the roentgenologic standpoint, is the elevation, swelling, coarseness and stiffness of the mucosal fold, the product of inflammation. The atrophic, erosive, and superficial ulcerative forms are usually difficult of detection. An inflammatory condition following gastroenterostomy may be indicated by swelling of the folds in the stomach and

efferent loop, and the roentgenologic diagnosis of gastrojejunitis, in experienced hands, is usually reliable. Apparently the most reliable roentgenoscopic evidence is that in which the inflammatory process was sufficiently extensive to give rise to gross defects. The question naturally arises as to how often gastric disturbances are the result of patchy or diffuse inflammatory states unrecognized in the absence of roentgenographic findings and in the absence of routine gastroscopic study. The gastroscopic appearance of the stomach in various forms of gastritis is instructively portrayed in the monographs or atlases of Schindler, Henning, and Moutier.

It is unfortunate that gastroscopy is such a highly technical procedure. In unskilled hands it is also a dangerous one. The circumspect physician cannot escape the conviction at times that some pathologists, gastroscopists and even roentgenologists or other protagonists of gastritis as an important entity, are unduly imbued with an enthusiasm comparable to that displayed on occasions by certain allergists and endocrinologists. One also gets the impression that the enthusiastic gastroscopist finds some abnormality of the gastric mucosa, to which he attaches undue significance, in the majority of cases in which he makes an examination. In this respect Katsch himself has pointed out the fallacy of a diagnosis made exclusively from the results of gastroscopic examination because, "a clear relation between gastroscopic findings and the clinical picture, even excluding everything but the subjective illness, can be established only in clear-cut cases with any degree of certainty."

The necessity for careful appraisal of all the facts, subjective and objective, as in other phases of medicine, is obvious. Careful teamwork among clinician, laboratory worker and surgeon is often essential in order that diagnostic and therapeutic problems in this field may be successfully surmounted.

REVIEWS

The Normal Diet and Healthful Living By W W SANSUM, R A HARE, and R BOWDLN 243 pages, 12 × 22 cm Macmillan Company, New York 1936 Price, \$2 00

This is a book intended for popular appeal, written by the authors to present in a permanent form, especially for their own patients, facts of general health interest. A bird's eye view is given of such topics as the elements of nutrition, the vitamins, the physiology of digestion, the "elimination of wastes," and many familiar medical disorders including indigestion, allergy, underweight and overweight and the care of teeth. Finally, there is a brief discussion of bacteriology, especially as it relates to focal infection, with particular emphasis upon the work of Dr E C Rosenow. The material which has been mentioned occupies the first 186 pages of the book. The remainder is taken up with the customary appendices to be found in such treatises, including a few words on menu planning, followed by the usual sample menus, food tables, and weight tables.

G A H

A Textbook of Obstetrics for Students and Practitioners By FRIDRICK C IRVING, A B, M D, F A C S 558 pages, 24 × 15.5 cm Macmillan Company, New York 1936 Price, \$6 00

Good textbooks on obstetrics are always timely. By sound conservative advice they advance the efforts of the profession to reduce maternal mortality.

In elaborating the outlines used in the teaching of students in the Harvard Medical School, the author has created a clear and useful textbook. In keeping with the avowed purpose of making the book concise, the author has intentionally avoided the history of obstetrics, and the presentation of all sides of controversial subjects, and frankly states that the work does not cover the entire field. The contents are discussed under the conventional headings, and the index is ample. With the exception of the roentgenogram reproductions, which for the most part are only fair examples of the subjects which they are intended to illustrate, all of the 357 illustrations are clear outline drawings many of which have been modified from other works to which due credit is given. Attention is called to the excellent bibliography to be found at the end of each chapter which should prove invaluable to students and practitioners using this book as a guide. The pathologic descriptions are thorough.

The author prefers pentobarbital and scopolamine as analgesic agents during labor and uses rectal ether to control excitement. The toxemias of late pregnancy are classified as preeclampsia and eclampsia. Gynoplastic repairs following delivery are definitely frowned upon as is also the so-called "prophylactic forceps" operation. One cannot but feel that the descriptions of operative procedures are given too much space, and that prenatal and postnatal care should be given more emphasis in any work intended for the student and practitioner.

The author states that the book represents the policies and practice of the Boston Lying-In Hospital, and from it we learn that such obstetrical complications as septic abortion, placenta previa, premature separation of the normally implanted placenta, and eclampsia are treated conservatively in that clinic. Of especial interest to the readers of this journal are the discussions of the medical complications of pregnancy. These are brief but give concisely the author's viewpoint as an obstetrician on such questions as the indications for the termination of pregnancy.

The book is well written, and since it presents the author's vast experience in obstetrics in a readable form, it should prove of definite value to the student and practitioner to whom it is warmly recommended

J E S

The Bacteriology of Typhoid Salmonella and Dysentery Infections and Carrier States BY LEON C HAVINS, M D, Director of Laboratories, Alabama State Department of Health First Edition 158 pages The Commonwealth Fund, 41 East 57th St, New York City

This small volume sums up certain investigations and experiences of the author while actively engaged in public health work in the field and laboratory In thirteen short chapters, each with its summary and bibliography, the more important characteristics of the intestinal bacteria are discussed and selected laboratory methods described Clinical bacteriologists will find the book of especial interest A sense of undue brevity and of incompleteness in some of the chapters may be explained by the fact that the work was posthumously published

S L J

Examination of the Patient and Symptomatic Diagnosis JOHN WATTS MURRAY M D Second Edition 1219 pages C V Mosby Co, St Louis 1936 Price, \$10 00

This work is an effort to present, in minute detail the procedure for obtaining a clinical history and performing a physical examination The book is divided into two sections, the first on history taking and general physical examination, the second on specific symptoms and physical signs of disease localized in organs or body parts

After a long introduction, the author presents an outline of history and physical examination, then proceeds to an extremely minute analysis of history taking, given in catechism, or question and answer form The answers are frequently cast in the shape of lists of diseases which may be related to certain conditions, an unfortunate method, since the lists are so long as to make this section almost unreadable

Many statements are introduced as facts which do not bear up under analysis For example, in the section on Past History, question five—"Has the patient ever had diabetes?"—is answered thus, "Pulmonary tuberculosis is perhaps the most frequent complication in consequence of diabetes, the diabetic state following its development"

Question eight "Patient ever had chlorosis or anaemia?" Answer "Chlorosis may give rise to gastric ulcer, exophthalmic goiter, amenorrhea" On Page 68 "Cardiac hypertrophy, cardiac valvular disease, atheromatous degeneration of the arteries, and aneurysm may cause hemorrhagic neuroretinitis" Page 70 "Floating kidney may cause dilatation of the stomach" These, and many other similar statements, are offered without explanation or qualification

In the second section diseases of specific parts or tracts of the body are considered Each division is preceded by some details of history and physical examination, again in question and answer form, with the answers suggesting the disease possibilities The reader is evidently expected to refer to the paragraphs describing those diseases, although specific references are not given Many of the disease descriptions are very good, especially those of the respiratory tract On the other hand, several very important ones are apparently missing entirely The index, for example, does not list lobar pneumonia, typhoid fever, or pernicious anemia, although these diseases are mentioned at times in the text

The reviewer doubts if this book could be of much help unless it were used simply as an aid to other texts Many suggestions in it are very helpful, but as a whole, it would be improved by condensation and rearrangement

T N C

Collected Writings of ALFRED F HESS with biographical memoir and bibliography
2 volumes, cloth, 1453 pages, illustrated Charles C Thomas, Baltimore 1936
Price, \$15 00

The more important scientific contributions of Alfred Fabian Hess have been collected, edited and published in two well bound, well printed volumes. Abraham Flexner wrote an appreciative and interesting biographical memoir which precedes the writings. In this sketch are traced the main events of Hess' life and the principle influences which shaped it. It contains as well a critical appraisal of his work as a scientist and investigator and the place he holds in pediatrics.

The collected papers represent some of the most important investigative work done in medicine during the first third of this century. Such broad topics as tuberculosis in infancy, the antiscorbutic vitamin and infantile scurvy, and the effect of irradiation of foodstuffs are discussed in the reports of numerous investigations. One is impressed at how much pioneer work this man did and how many accepted and well trod avenues of medical thought were either indicated or opened up by his researches. In addition to the above mentioned investigations there are papers on rickets, purpura, alimentary intoxication and various other pediatric problems. It is characteristic of these articles that they are short, well written and easy to understand. His complete bibliography is appended to the work.

In summing up Hess' position Dr. Edwards A. Park writes, "Dr. Hess was the foremost investigator among pediatricians in this country." "A great skirmisher on the forefront of scientific progress, with an almost uncanny eye for the point at which the next attack should be made, with a genius for predicting the course which investigation should take, with almost infallible judgment on the basis of slight evidence and simple experiment as to where the weak point in the armor of ignorance lay." "Hess was the best example of what can be accomplished in science by the ability to think alone and unaided."

These volumes are a valuable addition to the library of any one interested in medical and pediatric progress.

COLLEGE NEWS NOTES

GIFTS TO THE COLLEGE LIBRARY

Acknowledgment is made of the following gifts received recently for the Library of the American College of Physicians from the authors

- Dr Percy Brown (Fellow), Boston, Mass—1 autographed book, "American Martyrs to Science Through the Roentgen-Rays",
- Dr George B Eusternian (Fellow), Rochester, Minn—1 autographed book (with Dr Donald C Balfour), "The Stomach and Duodenum",
- Dr Frederick T Lord (Fellow), Boston, Mass—1 autographed book, "Lobar Pneumonia and Serum Therapy",
- Dr Herman O Mosenthal (Fellow), New York, N Y—1 autographed book, "The Diagnosis and Treatment of Variations in Blood Pressure and Nephritis",
- Dr William M LeFevre (Fellow), Muskegon, Mich—2 reprints,
- Dr Lewis J Moorman (Fellow), Oklahoma City, Okla—3 reprints,
- Dr Joseph M Perret (Fellow), New Orleans, La—13 reprints,
- Dr Maxim Pollak (Fellow), Peoria, Ill—1 reprint,
- Dr William B Rawls (Fellow), New York, N Y—3 reprints,
- Dr Martin J Synnott (Fellow), Deceased—1 reprint,
- Capt Elbert DeCoursey (Associate), M C, U S A—1 reprint,
- Dr Harold R Keeler (Associate), Philadelphia, Pa—5 reprints,
- Dr Arthur R Masten (Associate), Wheat Ridge, Colo—5 reprints

Dr Edward L Turner (Fellow), from 1931 to 1936 associate professor and professor of internal medicine, American University of Beirut, Beirut, Syria, has recently accepted the appointment of professor of medicine and head of the division of medicine at Meharry Medical College, Nashville, Tenn. He will spend his full-time with the work of the college and hospital in connection with the reorganization of the division of medicine

Dr Ralph M Fellows (Fellow), for sometime connected with the Menninger Clinic at Topeka, Kan, has accepted the superintendency of the Osawatomie State Hospital, Osawatomie, Kan

The Washington Society of Pathologists has elected the following officers for the coming year: Dr Roger M Choisser (Fellow), President, Capt Elbert DeCoursey (Associate), M C, U S A, Secretary-Treasurer

Dr Matthew Shapiro (Associate), New York City, has been appointed assistant professor of clinical medicine in Columbia University College of Physicians and Surgeons

Dr R H Kampmeier (Fellow), has left Louisiana State University Medical Center to accept an appointment at Vanderbilt University School of Medicine, Nashville, Tenn

Dr George A Gray (Associate), formerly of Abilene, Tex., has become Director of the Nolan County Health Unit, Sweetwater, Tex.

Dr John H Musser (Fellow), New Orleans, La., was the guest clinician on the program of the Post-Graduate Assembly of the North Carolina State Medical Society at Banner Elk, N C., August 20 to 21. The Post-Graduate Assembly is conducted on "Internal Medicine and Therapeutics."

The Committee on Arrangements included Dr R H Hardin (Fellow), Banner Elk, N C., Chairman, Dr C L Sherrill (Fellow), Statesville, N C., and Dr James W Vernon (Fellow), Morganton, N C.

Dr Wingate M Johnson (Fellow), Winston-Salem, N C., President-Elect of the North Carolina State Medical Society, delivered an address on "My Experience with Influenza", Dr Verne S Caviness (Fellow), Raleigh, N C., "Pneumonia", Dr C H Cocke (Fellow), Asheville, N C., Governor for North Carolina and Chairman of the Board of Governors, "Evolution of the Modern Treatment of Tuberculosis", Dr D W Holt (Fellow), Greensboro, N C., "Backache". Dr L B McBrayer (Fellow), Southern Pines, N C., Secretary and Treasurer of the North Carolina Medical Society, and also Dr Musser presented addresses on the evening of the banquet.

Dr George R Minot (Fellow) and Dr C Sidney Burwell (Fellow), Dean of Harvard Medical School, were among those who addressed the Boylston Medical Society, on the occasion of its one hundred and twenty-fifth anniversary recently. The Boylston Medical Society is probably the oldest students' medical school organization in America. The dinner was held at the Harvard Club. Dr Burwell is President-Elect of the Society.

Dr William G Herrman (Fellow), Asbury Park, N J., has been advanced from 1st Vice-President to President-Elect of the Medical Society of New Jersey. Dr Francis R Haussling of Newark, who was installed as President, resigned because of ill health, whereupon Dr Spencer T Snedecor of Hackensack, President-Elect, was advanced to the Presidency and Dr Herrman to the post of President-Elect.

Dr Warren Coleman (Fellow), New York City, is one of the Vice-Presidents of the Physicians' Home, which has been recently reorganized and which now plans a vigorous campaign to finance a permanent home for aged and infirm physicians.

Dr Guy C Jarratt (Associate), Vicksburg, Miss., has been reelected Secretary of the Mississippi State Pediatric Society.

Dr J Arthur Myers (Fellow), Minneapolis, Minn., and Dr Samuel H Snider (Fellow), Kansas City, Mo., are Vice-Presidents of the newly formed American Academy of Tuberculosis Physicians.

Dr Andrew C Ivy (Fellow), Chicago, has been elected Vice-President of the Chicago Society of Internal Medicine.

Dr Mark S Knapp (Fellow), Ann Arbor, Mich, has announced his resignation as executive secretary and director of medical research of the Rackham Fund, Detroit, a position he has held since the fund was created in 1934

Dr John D Dunham (Fellow), Columbus, Ohio, has been appointed to the city board of health, succeeding the late Dr Wells Teachnor, Sr

Dr Charles E Sears (Fellow), Portland, Ore, has been made President-Elect of the Pacific Northwest Medical Association

Dr Clayton E Royce (Fellow), Jacksonville, Fla, has been elected a Vice-President of the Chattahoochee Valley Medical Association

Dr Anthony Bassler (Fellow), New York City, and Dr Martin E Rehfuss (Fellow), Philadelphia, have been appointed President and Vice-President, respectively, of the American delegation to the International Congress on Hepatic Insufficiency in Vichy, France, September 16 to 18, 1937

Dr Newton G Evans (Fellow) is President of the Los Angeles Cancer Society

The pathology laboratory of Beth Israel Hospital has been dedicated in honor of Dr Isidore W Held, clinical professor of medicine at New York University College of Medicine, the dedication ceremonies taking place on Dr Held's sixtieth birthday. Among speakers at the dedication was Dr John Wyckoff (Fellow), dean of New York University College of Medicine

The sixty-sixth annual session of the Colorado State Medical Society was held at Glenwood Springs, September 9 to 12. Aside from the regular program, there was a presentation of the past presidents of the Society, in the order of their seniority. Dr Hubert Work (Fellow), Englewood, Colo, former President of the American Medical Association and Secretary of the Interior under President Coolidge, was presented as the senior living president of the Society. The banquet was dedicated to Dr Josiah N Hall (Fellow), Denver, for several years the Colorado Governor for the American College of Physicians, in recognition of his fiftieth year of attendance at the annual meetings of the Society. Dr Hall has been a member of the Society fifty-two years. He has been a president of the State Society, of the State Board of Health and of the State Board of Medical Examiners. He has served on the Judicial Council of the American Medical Association and has been a member of the House of Delegates at various times. Dr Hall has been professor of medicine at the University of Colorado School of Medicine for many years.

Dr Guy H Turrell (Fellow), Smithtown Branch, N Y, is Secretary of the New York State Sanitary Officers' Association, the name of which has recently been changed to the New York Health Officers' Association

Dr Wade W Oliver (Fellow), professor of bacteriology, Long Island College of Medicine, Brooklyn, has been elected Secretary of Health Research, Inc, a non-profit corporation recently formed by the New York City Department of Health to accept and administer funds offered for financing research in the city's laboratories. The department plans to open a convalescent serum center

Dr Henry M Moses (Fellow), Brooklyn, is the director of the medical service of the new Brooklyn Cancer Institute, opened at Kings County Hospital during September, as an independent clinical unit of the division of cancer of the city department of hospitals. Surgical and radiotherapy services under individual directors have also been established. The three directors will be responsible for clinical policy in general and for the treatment and care of patients individually. The institute is under the general administrative supervision of the medical superintendent of Kings County Hospital. There is a visiting staff of thirty-one physicians. Beds are to be used as far as possible for cases of doubtful classification and for recognized tumor cases requiring short hospitalization, in order that the patients still reclaimable may find facilities for care

Dr William V Wilkerson (Fellow), Highcoal, W Va, is president of the Boone County (W Va) Medical Society

Dr Daniel L Finucane (Associate), formerly of Glenn Dale, Md, has been appointed associate professor of clinical medicine at Georgetown University School of Medicine, Washington, D C

Dr J P Bowdoin (Fellow), Atlanta, Ga, has been elected Secretary-Treasurer of the Georgia State Child Health and Welfare Council

Dr Leon S Lippincott (Fellow), Vicksburg, Miss, has been elected Secretary-Treasurer of the Mississippi State Hospital Association, Dr Lippincott is also Secretary of the Mississippi State Charity Hospital at Vicksburg

Dr Franklin B Bogart (Fellow), Chattanooga, Tenn, has been elected Secretary-Treasurer of the Tennessee Radiological Society

The Texas State Heart Association has elected the following officers for the coming year: Dr Edward H Schwab (Fellow), Galveston, President, Dr George R Herrmann (Fellow), Galveston, Vice-President, Dr Robert M Barton (Fellow), Dallas, Secretary

Dr John G Young (Fellow), Dallas, Tex, is Vice-President of the Texas Pediatric Society for the coming year

Dr Walter B Martin (Fellow) and Dr Frank H Redwood (Fellow), both of Norfolk, have been elected President and President-Elect, respectively, of the Norfolk County (Va) Medical Society for the coming year

Dr Frank C Hodges (Fellow), Huntington, W Va , has been elected a Vice-President of the West Virginia State Medical Association

Under the Presidency of Dr David Riesman (Fellow), Philadelphia, the Interstate Postgraduate Medical Association of North America is holding its International Assembly for 1936 at St Paul, October 12 to 16

Dr W A Dearman (Fellow), formerly of Gulfport, Miss , has been appointed assistant superintendent of the Mississippi State Hospital at Whitfield

Dr W M Sheppe (Fellow), Wheeling, W Va , has been elected Secretary of the Ohio County (W Va) Medical Society for the coming year

Dr Martin E Rehfuss (Fellow), Philadelphia, clinical professor of medicine at Jefferson Medical College of Philadelphia since 1933, has been promoted to professor of clinical medicine

With warmest regards of your friend
J. H. Stuckey
November 29th 127.

OBITUARIES

DR JAMES MESCHTER ANDERS

James Meschter Anders, M D , Ph D , LL D , Sc D , the Nestor of Philadelphia's medical profession, the first Master of the American College of Physicians and its President during 1922-23, died at his summer home at Bluehill Falls, Maine, on August 29, 1936, aged 82

Dr Anders was born in Fairview Village, Montgomery County, Pa , on July 22, 1854, and received his education in the public schools of Norristown, Pa , and at the theological seminary, under the auspices of the Mennonite Church, at Wadsworth, Ohio In 1877, he graduated from the University of Pennsylvania School of Medicine and in the same year received his degree of Doctor of Philosophy

He served his internship at the Episcopal Hospital, Philadelphia, and, in 1888, became visiting physician to the same institution One year later Dr Anders was appointed visiting physician to the Medico-Chirurgical Hospital and in the same year was made a member of the visiting staff of the Philadelphia General Hospital

In 1889, Dr Anders became a lecturer on *Materia Medica* at the Medico-Chirurgical College, and one year later was elected Professor of Hygiene and Pediatrics In 1891, Dr Anders became Professor of the Theory and Practice of Medicine and Clinical Medicine in the Medico-Chirurgical College, a position he held with credit and honor for over twenty-five years Dr Anders was the author of a textbook known as the "Principles and Practice of Medicine," which passed through fourteen editions, and he was co-author of a "Text Book of Medical Diagnosis "

Dr Anders was a frequent contributor to medical literature throughout his long and distinguished career, over a hundred scientific articles being listed from his pen He was widely and favorably known as a conservative and helpful consultant by the medical profession, and his services were sought by practitioners, both at home and at distant points

Dr Anders was greatly interested in educational and civic problems afieid from medicine and, at the time of life when many physicians become both formalized and even crystalized in thought, possessed a clarity and breadth of vision inspiring to all who were fortunate enough to come into contact with him

Dr Anders was much interested in Preventive Medicine and advanced its interests by practical application of sound principles as well as by well thought out addresses before influential professional and lay groups

In 1923, he was made a Chevalier of the Legion of Honor of France and, in 1928, had the honorary degree of Sc D conferred upon him by his Alma Mater, the University of Pennsylvania Many other well deserved honors, medical, civic and national, were bestowed upon Dr Anders, but he

remained, as in the beginning, modest, unselfish, altruistic, and was possessed by an admirable desire to prove useful to his profession, his patients and to the general public weal

The American College of Physicians was very dear to the heart of Dr Anders and he devoted much time and thought to how this organization could best advance and uphold the interests of the medical profession and the public the profession serves

Dr Anders' death has caused the College to lose a much admired and beloved Master, the medical profession a skilled and devoted practitioner, and the world has lost a man of exemplary character who spent his long life in attempting to make the problems of others less difficult

E J G BEARDSLEY M D , F A C P ,
Governor for Eastern Pennsylvania

DR EDWARD GILMER THOMPSON

Dr Edward Gilmer Thompson (Fellow), Memphis Tennessee, died June 21, 1936, aged 52 years

Dr Thompson was born in Louisa, Virginia, August 29, 1884, and in his early years his family moved to Marianna, Arkansas, where he resided until he came to practice his profession in Memphis in 1913

He secured his preliminary education in the public schools of Marianna and later attended the Branham and Hughes Preparatory School. He received the degree of Bachelor of Arts at Vanderbilt University in 1907 and his medical education was obtained at the University of Pennsylvania from which he graduated with honors in 1911. He was a member of the Phi Delta Theta, Alpha Kappa Kappa and Alpha Omega Fraternities

Following his graduation in medicine he served a two year internship at the Episcopal Hospital in Philadelphia, Pennsylvania, and in 1913 began the practice of medicine in Memphis, Tennessee. He devoted his professional career to internal medicine, was a Fellow of the American College of Physicians and Associate Professor of Medicine at the University of Tennessee College of Medicine, held staff positions at the Methodist and John Gaston Memorial Hospitals and was on the staff of the Illinois Central Railway System

In 1917 he was among the first to offer his services to his country in the great war. With the rank of Captain in the Medical Corps he was a member of Hospital Unit P and for fourteen months was attached to Base Hospital 15 at Chaumont, France. Though quiet and unobtrusive Dr Thompson took an active interest in organized medicine, being a member of the Memphis and Shelby County Medical Societies, Tennessee State Medical Association, The American Medical Association and the Southern Medical Association

Edward Thompson was not only much beloved by a large clientele but he was a doctor's doctor, being the personal physician probably of more of

the Memphis medical profession than any other member of it. His strong sense of fidelity to his patients doubtless shortened his life. His personal traits of character were outstanding. Clean in word and thought and deed, faithful, conscientious and loyal to his high conception of his duty, no one ever heard a harsh or unkind word spoken of him. He was loved and deservedly trusted implicitly by everyone who knew him. Competent, dependable, wholly trustworthy, the profession in Tennessee can ill afford to lose him.

J. OWSLEY MANIER, M.D., F.A.C.P.,
Governor for Tennessee

DR. JAMES FRANKLIN ACKERMAN

Dr. James Franklin Ackerman (Fellow), Asbury Park, N. J., one of six sons of Joseph and Susan Ackerman, was born in Nashua, N. H., December 29, 1864. He received his preliminary education at Francestown Academy in New Hampshire and in the public schools of Shelburn Falls, Mass. He received a portion of his college training at Amherst College, followed by his medical training at the New York Homeopathic College, New York City, graduating in 1890. Thereafter he immediately went to Asbury Park, where he resided until his death on August 5, 1936. He was associated with his late brother, Dr. Joseph Ackerman, who died about a year ago.

Dr. Ackerman was highly regarded as a citizen in Asbury Park and was affectionately referred to as the "father" of two different hospitals, and at the time of his death was chief of staff of the Ann May Hospital, Spring Lake, and of the Fitkin Memorial Hospital, Neptune, which succeeded it. He was ex-president of the Asbury Park Medical Society, the Monmouth County Medical Society and the New Jersey State Homeopathic Society. He was an active member of the New Jersey State Medical Society, the New York Academy of Medicine and the American Medical Association. He had been a Fellow of the American College of Physicians since 1931.

Dr. Ackerman is survived by his second wife, Mrs. Anna Rouse Ackerman, a brother, George, of Nashua, N. H., and three daughters, Mrs. James A. Fisher, Mrs. Frank W. Cole and Miss O. K. Parry, all of Asbury Park.

Both the College and the medical profession have suffered a great loss in the death of this valuable member.

CLARENCE L. ANDREWS, M.D., F.A.C.P.,
Governor for New Jersey

DR. SIDNEY KOHN SIMON

"Sidney Kohn Simon, born, New Orleans, La., January 25, 1878, A.B., 1899, Tulane University College of Arts and Sciences, M.D., 1903, Tulane

University of Louisiana Medical Department, visiting physician, 1905-12, Charity Hospital, New Orleans, visiting physician, 1905 to date, and chief of Gastro-Intestinal Department, 1920 to date, Touro Infirmary, professor of gastro-enterology, Tulane University of Louisiana School of Medicine, member and ex-member of council, American Gastro-Enterological Association, member and ex-president, Southern Gastro-Enterological Association, ex-secretary and ex-member of council, American Society of Tropical Medicine, ex-secretary and ex-chairman of the Section on Gastro-Enterology, and Fellow, American Medical Association, member, Southern Medical Association and Southern Gastro-Enterological Club, Fellow of the American College of Physicians since 1928 "

Dr Simon has for years been regarded as an outstanding leader in his chosen specialty, gastro-enterology

His contributions to the literature of this field of medicine have been too numerous to mention at this time Suffice it to say that the influence of his writing and clinical teaching constitutes a living and lasting monument to his memory in the minds and hearts of the medical profession

J E KNIGHTON, M D , F A C P ,

Governor for Louisiana

THE POSTURAL SYNDROME RELATED TO OBESITY LEADING TO POSTURAL EMPHYSEMA AND CARDIORESPIRATORY FAILURE *

By WM J KERR, M D, F A C P, and JOHN B LAGEN, M D,
San Francisco, California

It is our purpose to discuss one of the most important syndromes seen in the practice of adult medicine, and to suggest measures for symptomatic relief based upon knowledge of bodily mechanics and function. We refer especially to a type of obesity which appears to be exogenous in origin, arising in persons whose dietary habits lead to a caloric intake beyond their daily requirements. It is not easy to determine whether individuals with the relaxed habitus are predisposed to the train of events which follows, but it is apparent that when medical attention is sought these patients present the posture of relaxation. The gradual accumulation of adipose tissue in the normal depots for fat gives the appearance of rotundity, and the state is usually designated as corpulency. The accumulation of fat in the third decade is relatively symptomless. Friends will comment on the gain in weight, and subjects will note the expanding girth with the attendant strain on buttons and realize that they must discard belts for suspenders. At this stage some dyspnea will be noted on exertion, and a few suffer from symptoms referable to strain of the spinal column.

In the fourth decade the appearance of the individual is one of increasing corpulency, with a tendency toward a florid complexion. The normal curves of the spine are accentuated. The added weight of fat of the abdominal wall and viscera moves the line of gravity forward, and to compensate for this the major portion of the thorax is moved backward, accentuating the lumbar curve. The upper part of the thorax and shoulder-girdle move forward, increasing the normal thoracic curve, and the head and neck are thrust forward as is required for adjustment at a new line of gravity.

* Received for publication March 12, 1936

The resulting strain on the spinal column and its mechanical devices for maintaining the erect posture is great. At this stage symptoms arise which bring the patient to the internist, the orthopedist, the neurologist, the gynecologist, and specialists in almost every branch of medicine. If treatment is directed to symptomatic relief alone, the results are rarely satisfactory and recurrences are frequent. The use of mechanical appliances and postural training does not remove the real cause of trouble which arises through the accumulation of fat with its added weight forward of the normal line of gravity. Under such circumstances, postural training can minimize the strain in some measure, but only by increasing effort as the protuberant abdomen gains in the race with the individual's ability to compensate.

The fifth decade marks the period of transition from the state of physical well-being and activity of youth to one of gradual lessening of activity of middle and old age. There frequently occurs at this time a change in the habits of living, distinguished chiefly by diminution of active exercise or even normal activity, and by increase in the consumption of food. Finally, it is at this time of life that changes occur in the body which herald the onset of presenile degenerations. These are the depositions of fat, increased flabbiness of muscles, atheromatous changes in the blood vessels and those gradual changes in skin, connective and glandular tissue which are difficult to define. These latter may be described as loss of elasticity and reparability with consequent lessened tone and poor response to injury such as strain in muscles and ligaments or pressure on bone and cartilage.

The foregoing is the fate of most individuals who live to a sufficient age, though the time of onset, the rapidity of progression and the degree of bodily change vary greatly. These normal changes are prodromal to the onset of the postural syndrome, in fact may be considered to pave the way for its development. The syndrome itself is certainly modified or delayed in susceptible individuals by proper exercise and diet. Heredity may be a factor in its development, as shown by the familial occurrence of arteriosclerosis, arthritis, premature gray hair and particularly corpulency. Environment is directly related. The condition singles out those individuals of sedentary occupation who have little facility or desire for exercise. It is also prone to attack those whose station in life is such that ease is second nature, over-indulgence in rich food is possible, and for whom press of business may limit exercise. The most obvious result is the gradual development of a heavy, pendulous abdomen, the paunch or "watermelon belly" which was at one time almost pathognomonic of the individual having reached a certain age or position in life.

MECHANICS OF POSTURE

The upright position of the human species is phylogenetically one that has been developed from the original four-footed position. The chief, if not sole, support in this new position is the spine. Its main function is that

FIG 1 Lateral view of spine (after Piersol Human Anatomy, Reproduced by permission of The Macmillan Co)

of a sustaining rod which maintains the upright position of the body and carries its weight. From the first cervical down to the last lumbar, the vertebral bodies constantly increase in mass corresponding to the increase of the weight-bearing stress from above downward, as it is finally transmitted to the sacrum which latter's five segments rapidly decrease in mass from above downward (figure 1). The spine is also a balancing rod which is wedged into the pelvic ring and serves as a post of anchorage for the muscles of the back, themselves partly concerned in maintaining balance. Equilibrium maintained by the body in an upright or standing position is active and not passive, and muscular forces must constantly be engaged in opposing and neutralizing gravitational forces. Phylogenetically, attainment of the upright position by man required special development of the extensor muscles of trunk, hips, knees and ankles.

Steindler asserts, "A law of statics states that any force, if applied to a body, can be resolved into a translatory force and a so-called couple of rotating forces, the latter being so arranged that a line connecting their points of application goes through the so-called center of gravity. This center of gravity represents the one mass-point of the body which is so situated that the gravital force for all other mass-points of the body can be imagined to go through it." In man, it is located at about the level of the second sacral segment of the spine midway between the spine and a vertical prolongation of the hip-joints, in the midline. To quote again, "As long as all the partial forces of gravity apply in the center of gravity and as long as this center of gravity falls directly over the supporting surface, then the body is balanced and the resistant counterforces apply forces co-linear and in opposite direction to the gravitational force." This may be graphically represented by the line of gravity. Viewed from a frontal plane, this line of gravity bisects the body into two symmetrical halves. Viewed laterally, the line of gravity arises from the supporting surface of the feet between ball and heel, passes through the ankle- and knee-joints, runs between the hip-joint and sacrum and through the upper ventral portion of the sacro-iliac junction, then runs upward behind the bodies of the lumbar spine, intersects the spine at the lumbothoracic junction, runs slightly in front of the thoracic spine, intersects the spine again at the cervicothoracic junction, runs slightly behind the cervical vertebrae, and touches the head behind the ear at the mastoid process (figures 2 and 3).

There is an inherent tendency in the individual to maintain the center of line of gravity at a constant relation to the points of support of the body. Usually the line of gravity falls about four centimeters in front of the center of the ankle-joint. If morphological changes occur in the body which attempt to move the center of gravity forward, for instance in pregnancy or in obesity, we see that this tendency is usually counteracted by an increased plantar flexion of the foot in the ankle-joint. Naturally this applies only to a certain degree, and excess weight will finally carry the center of gravity

forward, thus forcing the knees into flexion in order to bring the line of gravity forward also

MECHANICS OF RESPIRATION

The thorax is a semi-rigid cavity entirely shut off from the outside by the structures of the neck above, by the ribs and spine on the sides, and by the diaphragm from the abdominal cavity below. The thorax contains the

FIG 2 Vertebral column showing curves as seen actually and in silhouette (From Steindler's "Mechanics of Normal and Pathological Locomotion in Man", Courtesy of Charles C Thomas, Publisher)

- A Normal upright posture showing line of gravity and center of gravity
- B Intersections of the line of gravity
- C Dorsoposterior curves

heart, great vessels, esophagus, trachea and lungs, which latter alone interest us. The lungs may be considered as two large membranous sacs whose interior surface is multiplied greatly by subdivision into alveoli, all of which communicate freely, by gradually enlarging tubes (the bronchioles and bronchi), with the outside air. The atmospheric pressure on the alveoli expands the lungs until they fill the entire thoracic cavity not occupied by other organs, so that however the size of the thoracic cavity varies, the volume of the lungs must change accordingly. Normal respiratory movements consist of an active inspiration followed by a passive expiration, the former requiring muscular activity, the latter usually not, except during forced respirations. The amount of air that flows in and out with each normal

respiration is known as the tidal air, and averages about 500 c c for an adult male. The complementary air is the amount of air that can be breathed in over and above the tidal air by the deepest possible inspiration, it is about 1600 c c. Conversely, the supplemental air is the amount that can be breathed out, after a quiet expiration, by the most forcible expiration, it is also about 1600 c c. The vital capacity equals the tidal plus the supplemental plus the complementary air.

FIG 3 Types of posture (From Steindler's "Mechanics of Normal and Pathological Locomotion in Man", Courtesy of Charles C Thomas, Publisher)

- A Normal posture
- B Relaxed posture
- C Military posture

Each rib is attached to the spinal column at two points: the head to the body of the vertebra and the tubercle to the transverse process, so that up and down movements of the ribs result in a rotation around an axis joining these two points. Since the ribs slant downward to their attachment to the sternum, this with the rotation causes an enlargement in the dorsoventral

and lateral diameters of the chest every time the ribs move up, which is the act of inspiration. Therefore any muscle attached to the thorax whose contraction causes an elevation of the ribs must be considered an inspiratory muscle, and conversely, anything which elevates the ribs results in an inspiratory state of the thorax.

To the six lower ribs and to the xiphoid process are attached the costal and sternal portions of the diaphragm respectively, the lumbar portion attaches to the first, second, third and fourth lumbar vertebrae, and the thoracic portion to the thoracic vertebrae. From these attachments the muscular sheet extends ventrally along the walls of the thorax and then bends over to form an arch, with all the fibers inserting in the central tendon. This latter is not entirely free since the pericardium is attached to it, and may be considered as a tendinous attachment connected with the cervical fascia. A contraction of the diaphragmatic muscle draws the central tendon downward toward the abdominal cavity and therefore increases the size of the chest in the vertical diameter, while an increase in the thoracic cavity around the periphery of the diaphragm is caused also by the flattening of the muscular arch. Two results follow this movement: the lungs are expanded exactly in proportion as the cavity enlarges, which constitutes an inspiration; secondly, the descent of the diaphragm raises the pressure in the abdominal cavity, causing the abdominal wall to protrude. Expiration, as far as the diaphragm is concerned, is entirely passive, resulting from relaxation of the contraction, though aided by the abdominal pressure produced by inspiration, and still further, on forced respiration, by contraction of the abdominal musculature. Conversely again, anything which causes the diaphragm to descend results in an inspiratory stage of the thorax.

THE POSTURAL SYNDROME

Description The postural syndrome has as its basis obesity, which results in the development of a heavy dependent abdomen. It is this latter which is the obvious cause of the train of symptoms and signs that ensues. Their production depends upon two factors, unrelated except for cause, but synergic in effect. The first of these is the dragging effect exerted by the increased abdominal weight. This makes itself felt chiefly in the lumbar spine to which the weight is transmitted through muscle, fascia and skin. Here the result is at first an exaggeration of the normal lumbar curve, later an increasing lordosis with the vertebrae parting ventrally like the leaves in a book. The spine being intimately associated throughout its length, must compensate for this, which it does by causing a thoracic kyphosis and a cervical lordosis. The sacrum, normally at an angle of 45 to 60 degrees with the lumbar spine, is elevated to an angle of 90 degrees or more.

The second factor is concerned with the shift in the center of gravity produced by the excess weight which, as it were, has been attached to the front of the body. As mentioned previously, this is at first compensated for

by increased plantar flexion. When this is no longer effective, the individual is forced to compensate further, which he does by bending his knees and voluntarily increasing the lumbar lordosis through muscular action, the latter resulting also in the effect on the rest of the spine. A patient seen in lateral aspect reminds one of an individual who is attempting to "get in under" a heavy weight in order to support it more comfortably. This is somewhat

FIG 4 External resistance weight lifting (From Steindler's "Mechanics of Normal and Pathological Locomotion in Man", Courtesy of Charles C Thomas, Publisher)

A From the floor

B To shoulder height

C Upward lift

(Note the weight following closely in the line of gravity)

similar to that which is seen in the mid-stage of lifting an external weight, as shown in figure 4. Here of course some of the weight is supported by the muscles of the arm and shoulder, and exerts a drag on the upper part of the frame also. Note the bending of the knees and the increase in normal spinal curvature.

The governing principle is that the weight to be lifted never becomes too far deflected from the line of gravity, otherwise a rotation movement will

develop which is too great to be overcome by the working muscles. With the weight in the line of gravity, the individual has only the translatory weight-stresses to overcome, and he will avail himself of the skeletal resistances for this—that is, the resistance of the rigid bones—to the best possible advantage. An analogous situation is seen in patients with abdominal obesity. Here the center of gravity has been shifted forward from the line of gravity. In order to maintain this weight with the least muscular exertion and therefore the greatest comfort, the line of gravity (which is the optimum line of weight-bearing) must be carried forward. This is done, as already stated, by bending the knees and increasing the lumbar lordosis (figure 5).

FIG 5 Figures illustrating good and bad bodily mechanics, based on an examination of 700 Harvard freshmen (after Lee and Brown in "The Journal of Bone and Joint Surgery", reproduced by permission)

Group A 75%
Good mechanical use
of the human body

- 1 Head straight
above chest,
hips and feet
- 2 Chest up and for-
ward
- 3 Abdomen in or
flat
- 4 Back, usual curves
not exaggerated

Group B 12.5%
Fairly good mechan-
ical use of the hu-
man body. Note
changes from
Group A

- 1 Head too far for-
ward
- 2 Chest not so well
up or forward
- 3 Abdomen, very
little change
- 4 Back, very little
change

Group C 55%
Bad mechanical use
of the body. Note
changes from
Group A

- 1 Head forward of
chest
- 2 Chest flat
- 3 Abdomen relaxed
and forward
- 4 Back curves are
exaggerated

Group D 25%
Very bad mechanical
use of the body
Note changes from
Group A

- 1 Head still farther
forward
- 2 Chest still flatter
and farther back
- 3 Abdomen com-
pletely relaxed,
"slouchy"
- 4 Back, all curves
exaggerated to
the extreme

Whichever the mode of production, the effect of the increase in lumbar lordosis is the same, resulting as it must in the compensatory increase in the other normal spinal curves. This accentuation of the curves, coupled with the bending of the knees, causes a reduction of stature. The increase in cervical lordosis forces the individual to carry his head bent forward, the degree depending upon the lordosis. To maintain the head in the normal position puts extra work on the extensor muscles of the back of the neck, so a position of comfort unconsciously results in the bowing of the head. Thus, however, necessitates a strain on the extra-ocular muscles (recti-superior), it being easier to lift the eyes than to lift the head. Hypertrophic arthritis of the spine may be initiated, or exacerbated if already present. In particular, the radicular syndrome due to arthritis is usually made worse, or may make its first appearance when the increasing spinal curvature in the presence of the arthritis results in irritation of nerves.

The increased thoracic kyphosis is perhaps the most important effect of all in view of the result it has on respiration. This is of far-reaching importance and not limited alone to inspiration and expiration. Any increase in the normal curves of the thoracic spine, as shown by Kountz and Alexander, results in elevation of the ribs, producing thereby the barrel-chest seen typically in obstructive emphysema, but in this instance without marked emphysematous changes in the lungs. This flaring of the rib-cage also directs the lower ribs downward, which with the widening, flattens the diaphragm. Part of the mechanism that lowers the diaphragm and prevents their excursion is due to the visceroptosis.

Another significant fact is that these individuals are able to breathe with a great deal more facility when lying flat, since the relief from abdominal weight in the prone position must release the diaphragms. They suffer, not from orthopnea, but from *orthostatic dyspnea*.

There is therefore a double mechanism at work to keep the chest more or less fixed in the inspiratory phase. Consequently the tidal air is less than normal, while the complemental air is greatly reduced. Expiration may be even more affected than inspiration. There is little tendency for the chest to collapse or the diaphragm to raise at the end of inspiration, passive expiration is reduced. Expiration must now become somewhat of an active muscular exertion, and mainly thoracic since the marked visceroptosis prevents muscular exertion on the part of the abdomen to force up the diaphragm. There is not, however, the added impediment of bronchiolar narrowing as is seen in obstructive emphysema.

The reduction in pulmonary ventilation, leading to oxygen-debt on exertion particularly, results in dyspnea. This, as stated before, is orthostatic, occurring only in the upright position, but is not present on sitting or in the prone position. There is a compensation taking place, however, which is the occurrence of polycythemia in the advanced stages of the syndrome, brought on by the reduced oxygenation of the blood. This often produces

some cyanosis, or accentuates that already present. The late effects are on diminution of cardiac reserve from overstrain, constituting, in its effects on tissue-oxygenation, somewhat of a vicious cycle. Coincident arteriosclerosis complicates the clinical picture. Figure 6 shows in tabular form the inter-relationship of the syndrome.

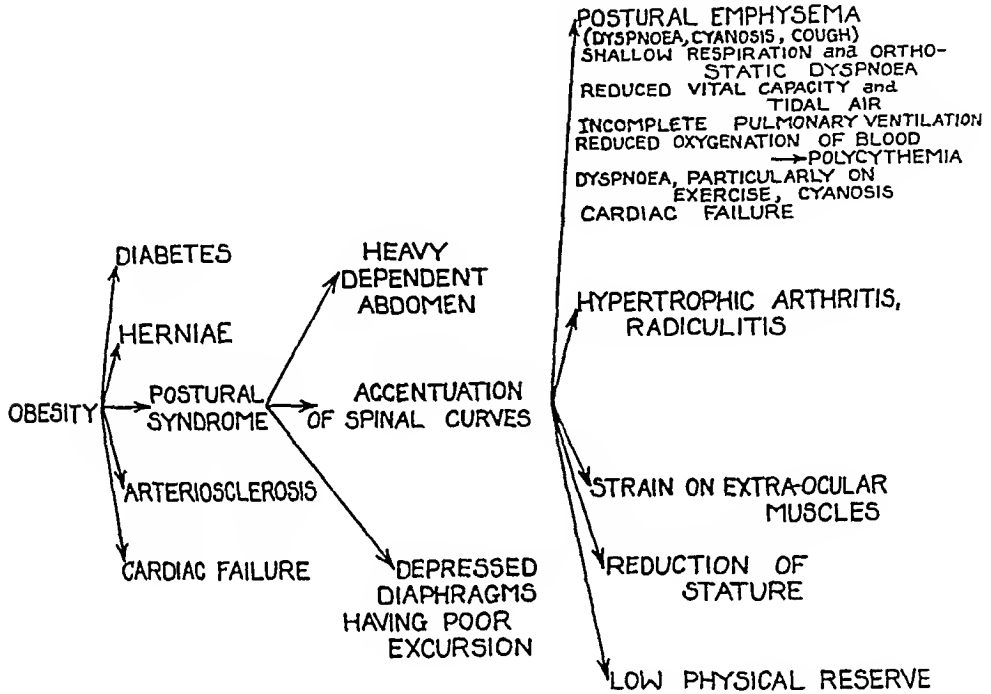

FIG 6 Schematic representation of the postural syndrome resulting from obesity

Symptomatology It is during the fifth and sixth decades that patients in this group are obliged to seek medical advice from the internist. The clinical syndrome is, as a rule, remarkably complete. The presenting symptoms are usually increasing *orthostatic dyspnea*, cough, cyanosis and edema, referable to the respiratory and circulatory systems. Along with these, or as chief symptoms, are radiculitis associated with "irritation" of nerve-roots, a group of less well-defined symptoms originating in the vertebral bodies, intervertebral discs and ligaments, symptoms resulting from muscular strain and weakness, including pains in the orbits associated with strain on the extra-ocular muscles and such obvious defects as ventral and inguinal herniae, symptoms of strain on the lumbosacral and iliosacral articulations, and symptoms of strain on the hip- and knee-joints and the arches of the feet.

The physical examination may be made for the first time with the patient in bed suffering from respiratory and circulatory symptoms. In such emergencies, the full clinical picture may not be readily appreciated. The extremely florid complexion, with cyanosis, cough and edema, direct one's attention to the cardiorespiratory apparatus. The emphysematous chest

interferes with proper examination of the heart The blood pressure is normal or slightly elevated The abdomen is full, and a large accumulation of fat locally is often mistaken for ascites The great protuberance of the abdomen can be appreciated only when the patient is able to stand The kyphos in the upper thoracic spine may be so marked that such patients while lying almost horizontal in bed, will hold the neck and head in a vertical position The examination of the blood shows usually a hemoglobin content above 100 per cent (Sahli), and the red blood cells above 5,000,000 per c c Percentages of hemoglobin of 110 per cent, and red cells above 6,000,000 are not uncommon The vital capacity at this, the late stage, is usually reduced With proper treatment for congestive cardiac failure, the balance is soon reestablished in most cases It is surprising to observe the promptness with which patients are able to rest in the recumbent position, in contrast to patients with congestive cardiac failure from other causes When these patients become ambulatory, they exhibit extreme examples of the postural defects which will now be described

The appearance of the patient when fully undressed, and when viewed at a distance from the side is one of extreme relaxation The most striking feature is the rounded protuberant abdomen, but upon further inspection it is apparent that the entire outline of the silhouette is altered The curves of the spine are all accentuated, there is a moderate or marked lordosis of the lumbar spine, the sacrum is more horizontal than normal, and the thoracic spinal curve is increased with the shoulders forward and the arms suspended in front of their normal position, the upper ventral thoracic region is depressed, the head and neck are well forward with the chin out, accentuating the increasing kyphos in the upper thoracic spine, the eyes are elevated to retain vision in a horizontal direction, the pelvis is rotated backward, and the legs are flexed at the knees The stature is shortened more or less, and sometimes patients state that they have lost two or more inches in height from their measurements earlier in life They have the appearance of stooping to avoid an overhead obstruction Several have remarked that their friends ask why they always stand as if they were entering a low tunnel (figure 7) They have the appearance in outline of women in the later months of pregnancy, which may be duplicated in the normal individual by holding in the hands or by suspending in front of the abdomen a heavy weight (figure 8) If such faults in the distribution of weight were not corrected by re-alignment through the shifting of other masses of the body, the individual would be unable to maintain the erect posture (figure 9)

A more detailed study of the skeletal alterations in this syndrome is of interest The lateral roentgenograms, when taken in the position naturally assumed by the patient, show well the accentuation of the spinal curves and some of the alterations of individual vertebrae and intervertebral discs In the two regions where lordosis is produced—namely, the lumbar and cervical segments—the vertebral bodies tend to separate at their ventral margins with

their articulating surfaces in line with radii converging at a point nearer to the spine than is normal. This is particularly striking in the lumbar vertebrae, which seem to spring apart ventrally like short leaves of a book. The intervertebral discs are wedge-shaped in appearance, filling the spaces. The

FIG 7 Types of posture showing effects on spine

- A* Posture, spinal curves and intervertebral discs normal
B Relaxed posture with accentuated spinal curves resulting from a pendulous abdomen
C Postural changes late in pregnancy similar to those in *B*, but which never persist long enough to affect the intervertebral discs

lumbosacral articulation is likewise wider open ventrally than normal, and the weight-bearing surface seems to be limited to a narrow zone at the dorsal margin of the junction. The sacrum lies more horizontal than is normal, and the upper inlet of the pelvis is tilted backward and downward with the accompanying elevation of the acetabulum. The femur is inclined forward from the vertical line at its lower end and the knee flexed slightly. In the thoracic spine the dorsal convexity is increased unless an associated ankylosing arthritis prevents this compensating movement. At some sector of the

thoracic spine the vertebral bodies tend to be compressed ventrally, and wedge-shaped, and the intervertebral discs share likewise in a similar deformity. The kyphos of the upper thoracic spine is sometimes very marked, with an appearance of the vertebral bodies resembling a crushing "jack-

FIG 8 Lateral views of women in the late weeks of pregnancy, showing accentuated spinal curves

knife fracture'. The margins of the vertebrae and their articulations with the ribs frequently show lipping and spurs designated as hypertrophic arthritis. In the degenerative changes accompanying old age, the mechanical factors in faulty posture probably determine the location of these changes and may be more important in their causation than is generally understood.

Examination of the thorax shows some of the obvious effects of the faulty posture. In the usual posture on relaxation, the ribs stand in a more horizontal position than normal and incapable of normal elevation and expansion of the lungs. With respiratory effort, such as is made when per-

forming the test for vital capacity, the full expansion can be attained in the uncomplicated case. The diaphragms move the normal distance, or nearly so, on effort, but in ordinary breathing in the upright position it is obvious on auscultation that the expiratory phase is prolonged. The upper and

FIG. 9. Silhouettes of a woman late in pregnancy and a man with a pendulous abdomen.

ventral portions of the lungs are hyperresonant, as well as the bases behind. The veins in the neck and of the shoulder-girdle may be distended. Fluoroscopic examination of the chest usually shows little or no cardiac enlargement in the early stages, and in many cases the heart appears small. The emphysematous areas show increased illumination. The diaphragms move downward readily on forced inspiration and it is of some interest to note

that toward the end of inspiration there appears to be a sudden acceleration of the movement, to be followed by a long and slow ascent of the diaphragm before the next inspiration (figure 10) The interference with the dia-

ORTHODIAGRAM OF MAXIMUM DIAPHRAGMATIC EXCURSION IN A PATIENT WITH POSTURAL EMPHYSEMA

B

ORTHODIAGRAM OF MAXIMUM DIAPHRAGMATIC EXCURSION IN A PATIENT WITH ASTHMA AND OBSTRUCTIVE EMPHYSEMA

Fig 10 Orthodiagrams of diaphragmatic excursion (after Kountz and Alexander in "Medicine", reproduced by permission)

phragmatic movements by the defects in posture, and the added weight of the visceral fat, combine to prevent normal aeration of the lungs. Hansson discusses the mechanical importance of good posture as follows: "The diaphragm arises from the costal cartilages, xiphoid process, transverse process of the twelve 'dorsal' vertebrae, and from ligaments of the psoas muscle. The diaphragm can only be anchored rigidly if the back is held in extension, and thus poor posture diminishes the diaphragmatic excursion. The stomach is attached to the diaphragm at the cardiac end, and the pyloric end is fixed to the body wall. The liver is partly suspended from the diaphragm, and the transverse colon indirectly, by means of the mesocolon. A great load is, therefore, carried by the center of the diaphragm which, at least partially, is held through the right pericardium by the continuation of the

cervical fascia This fascia is attached to the cervical spine and mastoid process It can be understood, therefore, how flexion of the head and neck relaxes the cervical fascia, causing a ptosis of the viscera in the lower abdomen and pelvis Thus, it is of importance to carry the chin in and the head back "

The vital capacity of the lungs early in the evolution of the syndrome is normal, but as the thorax changes shape after many years of faulty posture there is gradual reduction in vital capacity This is, in part, due to the great mass of fat in the upper abdomen, and in part to the loss of elasticity in emphysematous areas of the lung At first the contrast to obstructive emphysema is great, but in the terminal stage of postural emphysema the vital capacity may be markedly reduced also Of greater importance is the tidal air of ordinary respiration Although we have not been able to verify our impression that the tidal air is greatly reduced, because of the difficulties in getting patients to breathe without conscious effort under experimental conditions, there can be little doubt of such reduction under given circumstances One of the striking symptoms described by such patients is dyspnea in the upright position, which we have designated as *orthostatic dyspnea* Almost invariably, except in the terminal stages when secondary cardiorespiratory complications have arisen, such patients will be able to lie in the prone position without respiratory embarrassment The reasons for this are obvious when the foregoing comments are recalled the thorax is extended, the diaphragmatic attachments are now in a more fixed position and the *abdominal counterweight* which must be lifted at great expenditure of energy in the upright position now becomes a minor encumbrance during expiration The counterweight, through gravity, may now actually assist in the ascent of the diaphragm in expiration, and the elasticity of the lungs becomes a more effective agency in the exchange of gases These considerations must be kept in mind in treatment, and will be reviewed later on in consideration of the management of the patient

The respiratory and circulatory disturbances are complex and difficult to analyze The faulty exchange of gases apparently leads to a compensatory polycythemia, which in our series is relatively constant The facies of the patient is one of high reddish color with variable cyanosis of the lips and cheeks depending on the stage of the complications in the thorax The veins over the upper thorax and arms, and in the neck, are usually prominent, and sometimes the subclavian veins are mechanically compressed between the clavicles and the first rib These latter veins may empty well when the shoulders are elevated The heart may be small, normal or of large size, apparently depending on many factors Here we must consider the degree and stage of emphysema and the immobility of the diaphragm interfering with the filling of the right heart, the extent of pulmonary arteriosclerosis and state of the right heart, the extent of systemic and coronary arteriosclerosis with and without hypertension, and the deformity

of the thoracic spine The position and shape of the heart are influenced by the position and movements of the diaphragm Electrocardiograms show more often a tendency to right axis deviation, but sometimes left axis deviation especially in patients with hypertension Defects in the conduction system and arrhythmias may be observed in older subjects Cardiorespiratory complications usually lead to an untimely death

The radicular symptoms and signs are of frequent occurrence, extending over many years They are related to the deformities of the spine, and have been previously reported in a general discussion of the subject by Gunther and Kerr, and many others Of special interest in our patients with the postural syndrome has been the history of attacks of "lumbago," lumbosacral and sacro-iliac strain, sciatica, abdominal and thoracic crises, and "neuritis" of the cervical and occipital nerves In some cases abdominal and pelvic operations are performed unnecessarily About one-third of all patients referred to us for supposed cardiac pain have their symptoms on the basis of spinal disease in the thoracic region, and are relieved by correction of the postural defects "Pseudo-angina" can be interpreted only as false diagnosis Many patients are treated for pain of suspected cardiac origin, and are subjected to the anxiety which such an interpretation connotes, who could be restored to a comfortable and useful life Gunther and Sampson have reported on this subject from our clinic

The accumulation of fat in the abdominal wall is great in such subjects The lack of proper exercise and function of the abdominal muscles results in atrophy and the weight of the mass of fat within and without the peritoneal cavity causes stretching of these damaged tissues Herniae in the midline and at the sides of the recti abdominis muscles, especially at their upper ends, are of common occurrence Inguinal herniae are also frequently associated with strain on the abdominal muscles resulting from the extreme weight placed upon them at the nearly horizontal shelf which limits the protuberant abdomen just above the pubis

The association of arteriosclerosis and diabetes with the postural syndrome may be related to obesity or other causes However, these conditions frequently complicate the clinical problem and must be dealt with in treatment Pulmonary arteriosclerosis is sometimes an added burden to an already overworked cardiorespiratory apparatus

Diagnosis and Differential Diagnosis The diagnosis of the postural syndrome described is usually not difficult In the relatively symptomless period subjects show a tendency to increasing weight with emphasis on expanding girth The compensatory changes in the spinal curves are remarked Episodes of thoracic and abdominal crises and "attacks" of spinal origin designated as neuritis, sciatica, "lumbago," lumbosacral or sacro-iliac strain often cause the patient to consult the orthopedist, neurologist and gynecologist and less frequently the internist The "spinal adjuster" sees many of these patients, also, and frequently after relief is not forthcoming from general practitioners and specialists

The respiratory symptoms and signs are minimal in these early stages. There may be slight dyspnea on exertion but it is usually attributed by the patient to his gain in weight. Orthostatic dyspnea has not become marked.

With advancing years the effects upon the respiratory apparatus assume greater prominence and the evidences of strain upon structures supporting the deformed body in the upright position manifest themselves. The increasing distortion of the abdomen and the exaggeration of the spinal curves are obvious. The orthostatic dyspnea becomes pronounced. The patient shows a high color and frequently presents a slight polycythemia. The vital capacity is reduced slightly but the tidal air is apparently greatly reduced only in the upright posture. The symptoms and signs of radiculitis are often marked. The roentgenographic evidence of abnormalities in the spinal axis usually confirms and helps to explain the radicular manifestations.

In differential diagnosis we must consider obstructive emphysema and other pulmonary diseases, cardiovascular disease, especially generalized, and pulmonary arteriosclerosis which may be present in older subjects, and spinal disease leading to deformities and radicular symptoms. With advancing years it is not always easy to disentangle all the complicating factors which give rise to confusion in diagnosis.

Treatment Prophylactic treatment would, of course, be most rational. Unfortunately, those who have a tendency to exogenous obesity (those who could personally do something about it) disregard the laws of the conservation of energy through ignorance or neglect. Sedentary habits and over-indulgence in food are sure guides to obesity for a great majority of people approaching middle life. The automobile and other means for conserving energy are making the individual more toad-like. Attention to the diet and exercise will benefit the great majority of those who are approaching middle age. The cultivation of the postural reflexes will also be helpful for those with relaxed habitus.

It is unfortunate that those who manifest symptoms first in relation to spinal strain are treated improperly from a mechanical viewpoint. There may be justification for the use of casts, braces, strapping and other mechanical devices to carry the patient over the acute crisis, but, when this episode has subsided, other measures must be instituted to prevent their recurrence or the more serious results which develop through the coming years. The postural training and exercises, of which Goldthwait has been such an able exponent in this country, may be very helpful in overcoming the postural defects. They may postpone or minimize future complications. Support for the abdomen may likewise tend to restore the normal distribution of weight and line of gravity, but these measures are only makeshifts for the obese patient. There can be no real substitute for the removal of excess weight by whatever means are possible, but chiefly through restrictions in diet and increased exercise. When all these measures are combined

we can offer the best plan for restoration of normal function. Without reduction of weight and especially of the abdominal region, we are frustrated in our efforts to secure the best results.

In the treatment of our patients, mostly males in the fifth and sixth decades, most of whom have appeared in the later stages of the syndrome, we have been confronted with symptoms of marked severity. However, those with less marked symptoms have responded well to the same measures. The point of attack is in three directions, but with the same end in view:

- 1 Temporary elastic support of the pendulous abdomen
- 2 Reduction in weight
- 3 Postural exercises

1 *Elastic Abdominal Support*—It occurred to one of us that if the patient could be given an abdominal support to overcome some of the weight applied to the diaphragm during inspiration and to relieve the *counter-weight* during expiration, the tidal air would be greatly increased, the spinal curves would be straightened, and the line of gravity moved backward. If a belt were devised which gave abdominal support and if elastic materials were inserted in the belt at the sides of the abdomen, the tidal air could be further enhanced. These elastic materials would in effect serve as a method of giving the patient artificial respiration by assisting in the expulsion of gases from the lungs. The description of this belt is given, and view of the belt in position in figure 11.

Many belts have been devised and are used routinely for abdominal support. Their main purpose is to correct either obesity or ptosis of the abdomen by lifting and holding in the abdominal wall. They accomplish this by supplementing or replacing the abdominal musculature which has either lost its tone or, more usually, has become flabby and no longer functions properly. These belts are constructed in many ways, but all have similar materials and serve the same purpose. We have a collection of inadequate belts donated by patients, and these show great variation in type.

The belt that we are presenting embodies several new principles. As a whole it is not unusual, or very different from the many we have seen. However, it is constructed with the physiological function of the abdominal wall in mind, and is designed to supplement and aid the ventral muscles rather than to replace them. A tightly wound cloth binder would support the abdomen more efficiently but would not permit mobility necessary for respiration.

Figure 11 C shows the belt in place on a patient. Figure 11 B shows some of the details of construction. The supporter is made of coutil, pekin-stripe cloth and elastic goring, it is fastened on by stake-buckles and hooks.

The front sections and the back section are of double thickness. The outer layer is of high quality coutil, the inner of pekin-stripe cloth. The only difference between the two is in the softer and finer quality of the pekin-stripe material which, being next to the skin, prevents chafing. Both sections are tailored, or fashioned. There

* These belts have been made for us by the C. H. Hittenberger Co., 1103 Market St., San Francisco. We wish to express our appreciation to this firm for helpful criticism in the original designing of the belt and for their courtesy and care in fitting our patients.

are three double stays in the back section with a seam at each, which permits fashioning the supporter to fit the contours of the individual patient. The back section is $8\frac{1}{2}$ inches in height, and the stays are of whalebone. For conditions of extreme lordosis, the cloth section in back may be extended up to the twelfth thoracic vertebra, and have incorporated in its firm duraluminum or steel stays. The stays should not, however, be bent to fit the curve of the lumbar spine but should touch the body at only the upper and lower edges of the belt, allowing the middle to span or bridge the lordosed spine.

FIG. 11 Showing the details of the belt suggested for the treatment of obesity and postural emphysema, and the locations for measurements to be used in the construction of the belt.

The left front section (figure 11 C(1)) has the hooks attached to it. The right front section (figure 11 B(1)) has attached to it the straps carrying the buckles. The height of the front from top to bottom varies somewhat according to the circumference. For patients 38 inches in circumference at the crest of the ilium, a height of 9 inches is usually most satisfactory, if the patient is exceptionally tall a front height of 10 inches can be used to advantage, for patients of a circumference of 44 inches or more, a height of 10 to 12 inches is usually required. The left front section extends across the abdomen as a flap 6 inches long, padded between the two layers with strips of drusy-cloth. This provides a soft base for the straps to lie on. The width of each half of the cloth section across the front is considerably less than in the

usual supporter, being an average of $2\frac{1}{2}$ inches wide. The total width of the non-elastic front is about 5 to 7 inches, but this varies with the tightness of the belt. The front flap slips under the right side of the belt as it is tightened.

The elastic lateral sections (figure 11 C(3)) each are made of two pieces of firm elastic goring 6 inches wide and approximately 7 inches long placed one above the other. The two pieces overlap about 2 inches in the center, which gives greater support to the front center. The lower piece of goring on either side is set diagonally downward towards the front, exerting therefore an upward lift rather than a straight posterior pull.

The uplift strap (figure 11 C(4)) is a combination of elastic and non-elastic material. The front forked section consists of firm elastic webbing $1\frac{1}{2}$ inches wide. The latter extends to a buckle located toward the top of the supporter just back of the hips, allowing tightening or loosening of the strap as desired. The uplift straps, being placed diagonally, exert a supporting rather than a suppressing pressure on the lower abdomen.

The belt is fastened in front by means of six skate-buckles and hooks (figure 11 B(2)). The buckles are slipped over the hooks with the straps loose, each may then be individually tightened to the desired degree. The extra length of strap is held up by slots at the origin, rather than allowed to dangle.

Figure 11 A shows the measurements required in making up a belt when the patient is not able to be fitted personally. The measurement for the upper edge of the belt is taken around the body about 1 inch above the anterosuperior spine of the ilium. The measurement for the middle of the belt should pass over the largest part of the abdomen. The measurement for the lower edge should follow the lowest line of the abdomen in front, and cross the spine in back three or four inches below the upper measurement.

The dimensions of a size-40 belt are approximately as follows:

1 *Back* $16\frac{1}{2}$ inches long at the top and 18 inches at the bottom, with three double pieces of whalebone $4\frac{1}{2}$ inches apart. Height is $8\frac{1}{2}$ inches.

2 *Elastic side-sections* 6 inches long made of two pieces of goring 5 inches wide with $2\frac{1}{2}$ inches' overlap, giving a height of 8 inches.

3 *Uplift strap*, the elastic arising at the bottom in front 5 inches long, continued by a web-strap $6\frac{1}{2}$ inches long, passing through a tightening-buckle and inserted into the beginning of the back-piece 2 inches below the top.

4 *Front sections* $2\frac{1}{2}$ inches wide and $9\frac{1}{2}$ inches high, the tongue 6 inches long.

It should be stated that these measurements do not designate the contouring necessary for proper fitting to the body, nor do they take into account the extra length required for seams, etc. They were taken from a finished product, laid flat.

Patients are taught to apply the belt before arising in the morning, preferably outside the undershirt. If a union-suit is worn, the belt can be worn underneath it over a thin garment. The patient should be in the supine position when putting on the belt, and the belt should be tightened from below upward. This is important in order to move the abdominal fat and viscera upward, rather than to compress it in the lower abdomen.

The unusual feature of the belt is the width and height of the elastic side-sections, particularly the width. This is obtained by making the front narrow, permitting the elastic side-sections to extend farther forward on the abdomen where the elasticity is much more beneficial than if it were placed toward the back. This increased elasticity permits expansion of the belt during inspiration. This aids, rather than suppresses abdominal breathing, and prevents limiting respiration to the thorax, as is seen in obese states naturally or where a firm, inelastic belt is applied. The increased elasticity also aids in expiration, and overcomes the prolonged expiratory period seen in those patients with depressed diaphragms due to abdominal ptosis or

emphysema The diaphragm more readily assumes the expiratory position, and is ready to descend with the next inspiration There is no decrease in the supportive effect during the inspiratory expansion

Other devices which provide support plus elastic pressure during expiration would serve the same purpose We have used belts made by inserting the elastic materials over the entire abdomen and back, with firmer materials at the sides with almost equal success Such belts in our opinion are more beneficial for relief of symptoms in obstructive emphysema than firm belts of the type used for visceroptosis

v

Fig 12 Postural correction by use of the belt described Figure on left shows position of extreme relaxation before application of belt

It has been our experience that patients who wear the belt when up and about are obliged to stand more erect, they breathe more freely, and are

relieved of orthostatic dyspnea. They may complain of some fullness after meals which can be controlled by loosening the upper straps. However, the belt may indirectly limit the desire to eat to excess although this is not suggested to the patient, advisedly. Since most of the patients are males we have refrained from using the term "corset" to designate this belt. The

FIG 13 Upper figures without belt lower with belt Left-hand figures made on first visit of patient, right-hand figures taken three months later. It should be emphasized that these are natural poses, no attempt made by the patient to exaggerate his posture.

continued use of the belt is perhaps helpful in removal of fat from the abdominal wall by continuous massage during respiration. Long continued use of the belt may weaken the abdominal muscles, but this result may be minimized by exercises which will be discussed later (figures 12 and 13).

We have observed that the color of patients improves promptly upon use of the belt. The brilliant color associated with the polycythemia diminishes, and cyanosis of the mucous membranes and nails is less striking. We have not followed a large enough series of patients long enough to secure accurate controls of the degree of polycythemia after treatment.

2 Reduction in Weight The plan for reduction in weight must be individualized for each patient, depending upon occupation, opportunity for exercise and general physical condition. A caloric intake should be determined which may be as low as 800 to 1000 calories for some patients. At first two or three pounds per week may be lost and later not more than one or two pounds per week until the patient approaches the ideal weight after a period of six months. In some of these patients the problem of dietary intake is a difficult one, as all who have treated obesity can testify. For the great majority, however, the severity of their previous disability, and the remarkable relief derived by use of the belt give them confidence in measures directed toward the source of their trouble. A silhouette of themselves from the side before treatment will often be a great stimulus for cooperation. The lessening of the girth due to loss of fat and improved posture will also lend encouragement.

3 Postural Exercises Chief among the postural exercises are those which educate the patient to stand properly until the postural reflexes assume command. This requires attention toward the correction of the position of relaxation. Patients should periodically stand with their backs to the wall touching the wall at as many points as possible. When some of the excess weight has been removed, the abdominal muscles may be strengthened by graduated exercises. The familiar admonition to "suck up the guts" employed by instructors in physical education may be very easy to accomplish by boys in their early years, but is almost impossible for the obese.

SUMMARY

The postural syndrome which begins with obesity in the relaxed type of individual and passes through a series of events with increasing protuberance of the abdomen and deformity of the spine, is discussed. The results of continued strain on the spinal axis and irritation of the spinal nerves are manifested by diverse clinical symptoms and signs which frequently bring the patient to specialists in many branches of medicine. The later complications in the abdominal wall, such as herniae, may be classed as "blow-outs" resulting from weakness of the retaining structures. The respiratory and circulatory manifestations are primarily due to interference with proper ventila-

tion of the lungs based upon postural defects and the disadvantages under which the diaphragm functions under the circumstances. The orthostatic dyspnea, reduced vital capacity and tidal air, polycythemia and cyanosis are closely related. In older subjects hypertension, systemic and pulmonary, and arteriosclerosis account for definite cardiac complications. Treatment requires temporary support for the pendulous abdomen and assistance in the evacuation of the lungs during expiration. A belt which gives this support and aids in expiration through the elastic force of materials inserted in the sides of the belt, is described. This we have found of great benefit in the early months of treatment. The weight should be gradually reduced to correct the distortion of the spinal axis and restore the spinal curvature. Postural training is of greater value after the adipose tissue has been reduced, but is of little value in the patient with a pendulous abdomen and a great counterweight of visceral fat which interferes with the ascent of the diaphragm during expiration.

CONCLUSIONS

The postural syndrome beginning with obesity leading to postural pulmonary emphysema and spinal-curve distortion is described, and measures are suggested for treatment which, in our hands, have been of value.

We wish to express our appreciation to Dr John B DeC M Saunders for his suggestions and helpful criticisms.

EMPHYSEMA REBREATHING, BASAL METABOLIC RATE DETERMINATIONS, VITAL CAPACITY

By HENRY M THOMAS, JR., M D, F A C P, *Baltimore, Maryland*

THE classical picture of pulmonary emphysema is accepted without question by physicians, pathologists and roentgenologists. The chest is barrel-shaped and remains in the position of inspiration—moves as a whole—with diminished expansion and calls into play the accessory muscles of respiration. The percussion note is hyperresonant with obliteration of the compensatory spaces and the breath sounds are soft and expiration prolonged and sighing. The descent of the bases may be diminished, abdominal breathing is increased, although in long, narrow-chested individuals the diaphragms may descend freely. The lungs at autopsy are pale and voluminous, do not collapse on standing and microscopically present dilated alveoli and infundibular passages, the walls of which are often ruptured, forming unusually large bullae. The elastic tissue of the lungs is broken and the smooth muscle of the bronchioles and air passages degenerated. There is often accompanying chronic inflammatory reaction with formation of fibrous tissue, and some writers even consider pulmonary fibrosis the forerunner and constant companion of pulmonary emphysema.

Until the etiologic factors are more clearly determined pure pulmonary emphysema (not acute, or compensatory, or senile) will remain a theoretical condition and will differ with each hypothesis. There is, for instance, the large school of thought which considers changes in the chest wall and spinal column responsible for the changes in the lung known as emphysema. Another, perhaps larger, school looks on the changes in the chest wall as secondary to the lung changes and caused by the effort, doomed to failure, to compensate by over distention for the innate inadequacy of the lung tissue. A third school¹ attempts to differentiate between two types of emphysema, (a) that which occurs from changes in the chest wall—*postural emphysema*, and (b) that which occurs from some form of bronchial obstruction—*obstructive emphysema*. The postural type—actually one form of senile emphysema—is associated with little or no impairment of respiratory function, since abdominal breathing manages to expand the lungs by increased diaphragmatic expansion and compensates for the functional disability of the chest wall. Obstructive emphysema is accompanied by dyspnea, often extreme, and it has recently been shown² that difficulty in breathing is exaggerated by imperfect use of the respiratory muscles and great improvement can be brought about by suitable muscle training.

We have remaining, then, after eliminating acute, compensatory, senile

* Presented in part before the American Clinical and Climatological Association, Oct 22, 1935. Received for publication July 2, 1936.

From the Medical Department of the Johns Hopkins Hospital.

and postural emphysema, a small group of cases of true emphysema of the so-called obstructive type. These occur frequently as a result of asthma or pulmonary fibrosis with or without bronchitis and almost always after long continued coughing. It will not profit us to discuss whether inspiratory or expiratory obstruction is important, or whether repeated localized infections cause compensatory emphysema elsewhere in the lung,³ which may become permanent, or whether hereditary tendency to degeneration of the pulmonary stroma is necessary. These and other points must be established if emphysema is to be prevented, but that time is not yet.

Now, although the clinical picture of emphysema, as I have said, seems to be clear and definite and is accepted as a matter of course, there actually exists much difficulty in ascertaining whether we are dealing with lungs which are merely hyper-resonant and distended but functionally efficient (postural), or whether true functional and pathologic (obstructive) emphysema exists. The fluoroscopic and roentgenographic criteria of emphysema fail in the same manner as do physical signs to provide reliable information, although the careful studies of Fray⁴ have improved this method of examination. With McCann, he has shown that measurements on the roentgen-ray film of the total area of the fully expanded chest when multiplied by the anteroposterior diameter of the patient's chest provides a figure which correlates excellently with total capacity of the lungs in normal young adults. By this method the expected vital capacity of an individual can be estimated and thus a calculated normal established.

The chemical changes which accompany emphysema are well known and recently have been carefully surveyed by McCann et al.⁵ These changes are thought by inference to be brought about by poor mixing of alveolar air and diminished and defective alveolar surface. The alveolar CO_2 is increased and the arterial CO_2 content is increased, the arterial oxygen content is reduced and there is an increased tolerance for high CO_2 tension in respired air.

The total lung volume, as estimated by Christie's⁶ oxygen dilution method, remains essentially unchanged, but vital capacity is reduced at the expense of complementary air and residual air is increased. McCann⁷ finds that when residual air is over 40 per cent of total capacity some degree of anoxemia exists and anoxemia increases more or less proportionally to the increase in the residual air. It has been assumed that an increase in residual air and decrease in vital capacity cause inefficient alveolar ventilation, which in turn leads to diminished oxygen saturation of the arterial blood. Either of these estimations (i.e., residual air or oxygen unsaturation of arterial blood) is closely correlated with dyspnea and is thought to afford a fair index of pulmonary efficiency. It seems clear, however, that neither one expresses an accurate measure of potential pulmonary efficiency for any given individual.

The elastic recoil of the lung is lost or impaired as shown by its failure

to collapse on opening the chest at autopsy and by reduction during life of the negative intrapleural pressure (Christie⁸) It has been suggested⁹ that the principal factor in the loss of power to recoil is not damage to the elastic tissue of the lung but is reduction of the surface tension of the layer of moisture lining the overdistended alveoli Correlation of loss of elastic recoil of the lung with functional respiratory impairment obviously is not available for clinical purposes

The symptoms produced by emphysema are usually thought of as those caused by deficient oxygenation of the blood during its passage through the lung and are mainly dyspnea and cyanosis with late cardiac manifestations and occasionally secondary polycythemia

In the course of subjecting a patient suspected of having angina pectoris to the rebreathing test devised by Baker¹⁰ I was struck by the amount of dyspnea and cyanosis produced in the patient at the end of two minutes, whereas an average individual can continue the test for five to seven minutes with little or no discomfort The test consists of partially filling a Benedict-Roth metabolism apparatus with room air, leaving the soda lime in the apparatus as usual, and allowing the patient to rebreathe into the closed system, thereby gradually removing the oxygen and providing a steadily lessening oxygen mixture, thus producing an increasing anoxemia Patients with angina pectoris usually experience cardiac pain in the course of four to six minutes, but rarely complain of dyspnea The patient was a man of 40 years whose complaint was substernal distress and dyspnea on exertion There were no signs of cardiac failure except dyspnea on exertion and he had the classical physical findings of pulmonary emphysema After the patient had returned to Florida it was borne in on me that this test might be used as a gauge of functional respiratory reserve Since that time I have tested by this method 18 other cases that presented various degrees of clinical emphysema, but in no other case has there been any evidence of increased susceptibility to reduced oxygen tension I am at a loss to explain its occurrence in the first individual It seems possible that the increased residual air which is present in cases of emphysema contains more total oxygen than exists in normal residual air and thus allows the rebreathing test to continue for an abnormally long time before producing noticeable dyspnea or cyanosis In any event rebreathing air in which the percentage of oxygen is constantly being reduced does not offer a means of diagnosing and measuring functional impairment of the lungs in emphysema

Observations on the basal metabolic rate were made in the usual manner by filling the cylinder once with oxygen and once also with room air It is interesting to note that there was no appreciable difference in withdrawal of oxygen from the closed system whether offered in room air or in a mixture approximating pure oxygen (figure 1) One may surmise from this observation that the usual method of determining the basal metabolic rate in patients with emphysema is accurate and not vitiated by the existence of

oxygen unsaturation of the arterial blood which is known to exist. Here again the large amount of residual air probably acts as a buffer to prevent unusually rapid absorption of oxygen. Actual observations on arterial oxygen unsaturation before and after each method are necessary to afford

FIG 1 Rebreathing test on a patient with advanced emphysema. The first curve represents the amount of oxygen withdrawn from room air and the second curve the amount withdrawn from pure oxygen approximately an equal amount.

conclusive evidence on this point and these were made in only one case which showed the characteristic changes.

Finally the graphic method of recording vital capacity was added to these observations and certain variations from the normal curves were noted. In using the Benedict-Roth apparatus 20.73 c.c. of gas will raise the spirometer bell 1 mm. and the vital capacity may easily be determined by measuring on the graph in millimeters the extent of deep inspiration and forced expiration and multiplying this figure by 20.73. This method also allows vital capacity to be divided into reserve, tidal and complemental air. Without exception the vital capacity of patients suffering from clinical emphysema is reduced.

Christie has pointed out that after deep inspiration patients with emphysema are unable to blow out as much reserve air as they can after a normal inspiration (figure 2). McCann confirmed this finding in some cases but not in others, and reproduced a curve from one patient in whom the complemental air was greatly reduced and the reserve air normal or increased. A factor which seems to have been overlooked in this test is the amount of CO_2 which is absorbed by soda lime during expiration. Following inspiration after the dead space (150 c.c. to 200 c.c.) has been washed

out the expired air contains 6 to 7 per cent of CO_2 , all of which is removed from the gas in the metabolism apparatus by the soda lime, causing a false lessening of the vital capacity and this false lessening appears on the graph as a shortening of the end of the downward arm which usually registers re-

FIG 2 Patient with moderate emphysema. Curve represents reduction in vital capacity and inability to exhale reserve air following deep inspiration.

serve air. This lessening occurs in normal individuals also. The true figure for vital capacity is more nearly approximated by starting with forced expiration after a normal inspiration and then measuring the amount of air inhaled by forced inspiration (figure 3).

From my tracings it was also noted that when breathing normally after a deep inspiration the former resting phase was reached only after 8 to 20 breaths (figure 3). I believe both of these changes are due to inefficient use of the chest wall and faulty habits of breathing rather than to the loss of pulmonary elasticity as has been previously hypothesized.

There is no reason to believe that the lung would shrink further from a partially distended state than it would from a fully distended one. Expiration is a passive movement during quiet breathing and becomes active only during dyspneic breathing. In a normal person, with normal chest wall-

FIG 3 Patient with extreme emphysema. Vital capacity is greater when test is begun with expiration. Former resting point is slowly regained after forced inspiration.

lung breathing mechanism, need for greater respiratory activity is supplied by more rapid ventilation of a normal or temporarily slightly increased residual air. This is done by larger inspiratory movement followed by an associated active expiratory movement with the result that the proportion of tidal air to residual air is increased. In other words the life long habit of response to the need for more rapid ventilation of the lungs is an increased inspiratory effort with only a secondarily increased expiratory effort.

When, for whatever reason, residual air is permanently increased as it is in emphysema, tidal air is constantly increased to maintain the required residual air/tidal air proportion. This increase in tidal air on top, as it were, of an increased residual air encroaches on complementary air and brings about breathing at a higher and less efficient resting point. The larger residual

FIG 4 Basal metabolic rate determinations before (above) and after (below) subtotal thyroidectomy. Respiratory rate is practically the same in the two tests whereas tidal air is increased in the hyper- and decreased in the hypothyroid state.

air could be more rapidly ventilated when need be if tidal air could be increased partially at the expense of residual air but the life long unconscious training of forced breathing is in the direction of voluntarily increasing

inspiration and allowing expiration automatically to keep pace. In patients with emphysema the act of forced expiration is unable to keep pace with forced inspiration as is seen in figures 2 and 3. Reserve air can be expired only when forced expiration starts from the top of tidal air, that is, from the end of a normal unforced inspiration. For this reason in our clinic we are training emphysema patients to start the respiratory cycle with forced expiration and to allow inspiration to take care of itself. It is too early to report the results of this practice but temporarily improved breathing has been noted.

Studies of tracings made during basal metabolic rate determinations of patients before and after treatment for hyperthyroidism (figure 4) in individuals possessing a normal respiratory apparatus reveal that tidal air is increased in the hyper- and reduced in the hypothyroid state while the respiratory rate remains the same. However, it has long been known (Peabody¹²) that vital capacity is reduced in hyperthyroidism and in like manner the residual air recently has been reported (Robb and Weiss¹³) to be increased in hyperthyroidism and to diminish with improvement in the condition. It is evident, then, that changes in the subdivisions of total pulmonary capacity may depend on functional requirements and need not predicate structural change. Similar changes have been found in patients suffering from congestive heart failure and to this state in these, as well as in patients suffering from hyperthyroidism, the term "functional emphysema" has been applied. This term has been evolved to express the similarity of changes occurring in the subdivisions of total pulmonary capacity in cases of emphysema on the one hand and hyperthyroidism and congestive failure on the other. An effort has been made to carry the similarity further and to describe changes in alveolar blood volume which would reduce the elasticity of, and stiffen, the pulmonary tissue and in this and other ways reduce pulmonary efficiency in a manner similar to emphysema. In the hyperthyroid patient however, we know that the lung is adequately supplying an increased body oxygen requirement. Is it not reasonable to suppose that an augmented residual air which is properly ventilated by increased tidal air offers a simple way of meeting an increased oxygen demand? That these patients are dyspneic on exertion may be explained by the elevated resting point which in turn necessitates overextension of the chest early in the process of overventilating, but this tendency to dyspnea does not indicate that the respiratory apparatus is not functioning unusually well while the patient is at rest. Seen in this light the condition hitherto alluded to as "functional emphysema" might now be considered as a normal response to an increased demand for oxygen. It seems fair to inquire whether certain changes noted in emphysema patients also may not depend on functional requirements rather than changes in the lung parenchyma.

CONCLUSIONS

1 Rebreathing air containing a gradually diminishing oxygen percentage has not been shown to serve as a test for respiratory functional disability in patients thought to have clinical evidence of emphysema

2 Basal metabolic rate determinations in patients with emphysema seem to yield reliable results

3 It is important to realize that increase in residual air may constitute one factor in a method of increasing oxygenation of the blood and should not be accepted per se as evidence of reduced pulmonary efficiency

4 The term "functional emphysema" should not be used since it implies knowledge of emphysema not yet available and may lead to false hypotheses

5 Reeducation in breathing offers symptomatic improvement to patients suffering from emphysema

CLINICAL STUDIES ON VERODIGEN, A DIGITALIS GLUCOSIDE

By J P BAKER, JR, M D, and NATHAN BLOOM, M D, *Richmond, Virginia*

VERODIGEN, a gitalin-like fraction of digitalis, has been used for a number of years in several European countries, and in some instances has largely replaced the galenical preparations of digitalis. There have been a number of reports on its usefulness,^{1 2 3} which give the impression that it is considered superior to digitalis in several ways. From a clinical standpoint it is said to be absorbed more readily and to exert its effect on the heart more rapidly than digitalis. It is claimed, moreover, that this drug is borne by the gastrointestinal tract better, causing nausea and vomiting less often than digitalis.

In this country, Verodigen has been used but a few years. Stroud et al⁴ conducted both pharmacological and clinical studies, finding the qualitative effects of Verodigen to be the same as those of digitalis leaf. By biological assays they found the drug to be 130 times as potent as digitalis, and clinically, to be 360 times as strong—i e, 1/240 gr of Verodigen was found to be equivalent to 1.5 gr of digitalis leaf. These investigators were able to secure complete digitalization with from 1/10 to 1/16 gr, given over a period of five to six days.

In our study, we have used Verodigen on unselected cases of congestive heart failure, both those showing a normal sinus rhythm and those with auricular fibrillation. The group of cases studied in the hospital were kept in bed at conditions as nearly uniform as possible until compensation was restored. In the great majority of cases, no other drugs than occasional sedatives and opiates were used. The ambulatory cases were examined at the out-patient department about once every week. None of these cases had received other digitalis preparations for at least a month before the beginning of Verodigen.

Brief histories of the cases studied in the hospital follow. Table 1 gives the essential features in these cases on admission to the hospital (top line) and after the maximum therapeutic effects had been obtained with Verodigen (bottom line). In those cases showing auricular fibrillation the apical and radial rates are separated by colons.

ABSTRACT OF HOSPITAL CASES

D 1, a 41 year old colored male, on admission to the hospital (4/22/35) complained of shortness of breath on exertion for two or three months and swelling of

* Lost some by vomiting on second day Developed extrasystoles sixth day
† Lost some by vomiting on first and second days

the ankles for two months. He had continued at work until three weeks prior to admission, when he became too dyspneic. During the past week, edema gradually involved the legs, thighs, scrotum and penis. He had some bloody expectoration four days before admission.

Physical examination revealed marked orthopnea and engorgement of the neck veins. The apex of the heart, in the fifth interspace, extended to the anterior axillary line. Heart sounds were distant. A systolic murmur was audible at the apex. Occasional runs of extrasystoles interrupted an otherwise normal rhythm, the rate being 98. Blood pressure 170 systolic and 130 diastolic. The lungs showed moist râles over both bases with flatness to percussion over the right base. The liver was palpable well below the costal margin, and a fluid wave could be elicited in the abdomen. The sacrum, genitalia and extremities showed marked pitting edema. A seven-foot roentgenogram showed a transverse diameter of the heart of 21.2 cm and of the thorax of 34.6 cm.

Laboratory studies: slight anemia, urine—albumin, trace; occasional red and white blood cells and hyaline and granular casts, Wassermann + plus.

Cardiovascular diagnosis

- A Arteriosclerosis, hypertension
- B Cardiac enlargement, myocardial fibrosis
- C Regular sinus rhythm
- D Class III

On the evening of admission, Verodigen was started and a total of 11/80 gr was given in the next three days. During this time the pulse gradually fell to 80 (subsequently to 70), the vital capacity increased to 2300 cc (three days later to 3200 cc), râles in chest, enlarged liver and peripheral edema cleared up entirely, and there was marked diuresis. It is not to be thought that Verodigen was wholly responsible for the weight loss and diuresis, for 1 cc of Salyrgan was given on three successive days.

G J, a 47 year old colored male, was admitted to the hospital 4/13/35 with a history of two spells of breathlessness, 14 and 11 months previously, both of which had been relieved by some medicine prescribed by his family physician. Three weeks prior to admission, breathlessness returned, as well as several mild attacks of nocturnal dyspnea. Orthopnea had been present in the past few weeks. No history of edema. A past history was given of "bad blood" 12 years ago, for which he received 20 injections in the arm.

On physical examination he appeared slightly dyspneic and orthopneic. The neck veins were not distended. The apex beat of the heart was in the fifth interspace at the mid-clavicular line. There was a systolic murmur at the apex and a markedly accentuated, amphoric pulmonic second sound. The rhythm was regular, the pulse 128, blood pressure 170 systolic and 115 diastolic. The lungs showed numerous moist râles over both bases. There was no enlargement of the liver or peripheral edema. A seven-foot roentgenogram of the chest showed the transverse heart shadow to be 14.6 cm, of the chest 27.9 cm.

Laboratory studies: urine and blood essentially negative. Wassermann negative.

Cardiovascular diagnosis

- A Arteriosclerosis, hypertension
- B Cardiac enlargement
- C Regular sinus rhythm
- D Class II b

Verodigen administration was begun the day of admission, a total of 6/80 gr being given in three days. At the end of this time the pulse had dropped to 80, orthopnea and râles had cleared up and other changes taken place as shown in table 1.

He was continued on a daily dose of 1/240 gr Verodigen until and after discharge on 4/20/35

W G, a colored male, 36 years old, was admitted to the hospital 4/17/35, complaining that nine months previously he had begun having a feeling of fullness in the chest and attacks of paroxysmal dyspnea, especially at night. About the same time he began having a troublesome cough, nocturia and some swelling of the feet. Six months ago he took some heart medicine prescribed by his family physician which did not relieve him much so he has taken none for the past three months. Inquiry into his past history revealed the fact that he took eight injections "for his blood" two years ago, and that he was operated on for an ischio-rectal abscess in 1932.

On physical examination he showed slight engorgement of the neck veins. His heart was enlarged, the apex beat being 14 cm from the mid-sternal line in the sixth interspace. There was a prolonged diastolic murmur heard over the aortic area and systolic murmur over the apex and aortic area. The rhythm was suggestive of gallop, rate 120. Blood pressure was 160 systolic and 60 diastolic. Moist râles could be heard over the bases of both lungs. The liver edge was palpable and there was moderate pitting edema of the ankles. A seven-foot roentgenogram of the chest showed the transverse heart shadow to measure 19.6 cm, the chest 29.2 cm.

Laboratory studies: urine essentially negative. Blood showed moderate anemia. Wassermann 4 plus.

Cardiovascular diagnosis

- A Syphilis
- B Cardiac enlargement, aortic insufficiency
- C Regular sinus rhythm
- D Class II a

He received 5/80 gr Verodigen the day of admission with a fall in pulse rate to 80, and 1/80 gr the day after admission, following which his pulse rate dropped to 76 and remained at that level. He was given a maintenance dose of 1/240 gr daily. Within four days, all signs of congestive failure had cleared up.

H L, a 49 year old colored man, was admitted to the hospital 4/23/35 with a history of having caught cold and begun to cough three weeks previously. Following this he developed marked breathlessness and orthopnea. He had had nocturia three to four times since onset of present illness. Nine years ago he had both legs amputated above the ankles on account of frost bite.

Physical examination revealed marked orthopnea and slight engorgement of the neck veins. The heart was slightly enlarged, the apex beat being just outside the mid-clavicular line in the fifth interspace. There was a systolic murmur at the apex and an accentuated P. The rhythm was normal, rate 100. Blood pressure was 125 systolic and 105 diastolic in both arms. The chest was emphysematous in type, and there were dullness and râles over both bases. The liver edge was palpable four fingers below the costal margin, and there was moderate pitting edema of the abdominal wall and over the sacral region. Both legs had been amputated about the middle of the tibiae. A seven-foot roentgenogram of the chest showed the transverse diameter of the heart to be 18.1 cm, of the chest 30.6 cm.

Laboratory: urine and blood essentially negative. Wassermann 4 plus.

Cardiovascular diagnosis

- A Unknown
- B Cardiac enlargement
- C Regular sinus rhythm
- D Class III

On the day following admission he was started on Verodigen and received 8/80 gr in the space of three days. During this time his pulse rate dropped to 84, and

signs of congestive failure showed considerable clearing, within two more days they had disappeared altogether. He was given a maintenance dose of 1/240 gr and remained comfortable.

E W, a 52 year old white woman, was admitted to the hospital 5/14/35 complaining of paroxysms of dyspnea accompanied by cough, which had begun 15 months previously. These symptoms were much worse when lying down. In the past few days she has noticed swelling of the ankles.

Physical examination revealed an obese woman quite orthopneic, with neck veins markedly engorged. The heart was enlarged beyond the mid-clavicular line, the extent being impossible to judge on account of her obesity. The rhythm was suggestive of a gallop type, rate 120. Blood pressure 160 systolic and 110 diastolic. Asthmatic breathing could be heard over the upper chest, and numerous moist râles over the bases. The liver was palpable and ascites present. There was moderate pitting edema over the ankles. A seven-foot roentgenogram of the chest showed the transverse diameter of the heart to be 19.7 cm, of the chest 27 cm.

Laboratory studies unimportant.

Cardiovascular diagnosis

- A Arteriosclerosis, hypertension
- B Cardiac enlargement, myocardial fibrosis
- C Regular sinus rhythm
- D Class III

The administration of Verodigen was begun the day of admission and a total of 14/80 gr given in six days. Vomiting on the second day probably excluded 1/80 or 2/80 gr. During this time the heart rate slowed to 70, and practically all signs of congestive failure cleared up. On the sixth day extrasystoles were observed clinically and electrocardiographically, but there were no other signs of over-dosage. The drug was withdrawn for four days, following which the pulse ranged from 80 to 84. She was discharged on a maintenance dosage of 1/240 gr.

J M, a 52 year old colored man, was admitted to the hospital 7/17/35 with a history of dyspnea on exertion for the past four weeks with progressive swelling of the lower extremities. During this time he suffered with orthopnea and occasional attacks of paroxysmal nocturnal dyspnea. During the past week he has had a non-productive cough and dull aching pain over the heart. No previous history of decompensation.

On physical examination he was seen to be orthopneic, with marked engorgement of the neck veins. The apex beat of the heart was in the sixth interspace at the anterior axillary line. The rhythm was grossly irregular, the apical rate 126, radial 76, blood pressure 170 systolic and 86 diastolic. Peripheral arteries were tortuous and sclerosed. The lungs showed moist râles over both bases. The liver extended down almost to the umbilicus and there was pitting edema as high as the knees. A seven-foot roentgenogram of the chest showed the transverse diameter of the heart to be 23.8 cm, of the chest 32.2 cm.

Laboratory urine and blood essentially negative. Wassermann 4 plus.

Cardiovascular diagnosis

- A Arteriosclerosis, hypertension
- B Cardiac enlargement
- C Auricular fibrillation, established
- D Class III

Verodigen administration was begun the day of admission, 9/80 gr being given in four days, and 1/240 gr daily thereafter. There was a progressive improvement in symptoms and physical signs, coincident with a slowing of the ventricular rate and decrease in the pulse deficit. Within eight days all signs of decompensation had disappeared, and he was discharged later on a daily dose of 1/240 gr Verodigen.

Jos M, a 43 year old colored man, was admitted to the hospital 8/11/35 complaining of dyspnea on exertion for the past two months. He had to stop work three weeks ago since when his dyspnea has become progressively worse. A productive cough and nocturnal dyspnea have been troublesome features. Recently his feet and ankles have begun to swell.

Physical examination revealed moderate engorgement of the neck veins. The apex beat was 14.5 cm from the mid-sternal line in the fifth interspace. The rhythm was normal, rate 114. Blood pressure 216 systolic and 156 diastolic. The lungs showed moist râles over the bases and musical râles throughout. The liver was palpated 5 to 6 cm below the costal margin. There was pitting edema over the sacrum and of the extremities as high as the thighs. A seven-foot roentgenogram showed the transverse diameter of the heart to be 17.3 cm, of the chest 29.1 cm.

Laboratory urine showed a slight trace of albumin and rare hyaline casts. Blood showed moderate secondary anemia. Wassermann negative.

Cardiovascular diagnosis

- A Arteriosclerosis, hypertension
- B Cardiac enlargement
- C Regular sinus rhythm
- D Class III

Verodigen administration was begun the day following admission and a total of 9/80 gr given in three days following which 1/240 gr was given daily. During this time the heart rate slowed to 68 and all signs of congestive failure cleared up. The diuresis and loss of weight in this case were due largely to the use of Salyrgan.

W M, a 60 year old colored man, was admitted to the hospital 8/9/35. For the past four months he has suffered with dyspnea on exertion, which has grown steadily worse. Three weeks ago his feet and ankles began to swell. For the past two weeks he has had frequent attacks of paroxysmal nocturnal dyspnea.

Physical examination revealed slight engorgement of the neck veins. The apex beat was 16 cm from the mid-sternal line in the sixth interspace. The rhythm was normal, rate 108. Blood pressure 216 systolic and 100 diastolic. There was marked sclerosis of the peripheral arteries. Musical and sibilant râles could be heard over both lungs, most marked over the bases. The liver was not palpable, but the extremities showed pitting edema as high as the knees. A seven-foot roentgenogram showed the transverse diameter of the heart to be 18 cm, of the chest 27.9 cm.

Laboratory urine and blood essentially negative. Wassermann negative.

Cardiovascular diagnosis

- A Arteriosclerosis, hypertension
- B Cardiac enlargement, myocardial fibrosis
- C Regular sinus rhythm
- D Class II b

The administration of Verodigen was begun the day of admission and a total of 12/80 gr given over a period of eight days, with a fall in pulse rate to 80 and a simultaneous clearing of the signs of decompensation. In this case diuresis and weight loss can be attributed largely to Verodigen for no diuretics were given.

R D, a 64 year old colored female, was admitted to the hospital 9/8/35. She gave a history of dyspnea on exertion and occasional mild attacks of paroxysmal dyspnea for one month prior to admission. She had also had a non-productive cough, edema of the right ankle and nocturia. She had a severe attack of paroxysmal dyspnea just before admission, which caused her to seek hospitalization. Past history negative for cardiac symptoms and anti-syphilitic treatment.

Physical examination, after relief of the immediate attack by morphia, revealed orthopnea and moderate engorgement of the neck veins. The apex beat of the heart

was felt in the sixth interspace at the anterior axillary line. A systolic murmur was audible over the apex. Frequent extrasystoles were present. Pulse 110. Blood pressure 220 systolic and 116 diastolic. There were numerous moist râles over the bases of the lungs. The liver was palpable 3 to 4 cm below the costal margin, and there was slight pitting edema of the ankles. A seven-foot roentgenogram showed the transverse diameter of the heart to measure 17.9 cm, of the thorax 24.6 cm. A large saccular area extended from the ascending aorta, thought to be aneurysm (confirmed later by fluoroscopy).

Laboratory. Blood—moderate anemia, urine—essentially negative. Blood Wassermann and spinal fluid Wassermann negative.

Cardiovascular diagnosis

- A Unknown
- B Aneurysm of ascending aorta, cardiac enlargement
- C Premature ventricular contractions
- D Class III

Verodigen administration was begun the day after admission, a total of 7/80 gr being given in two days, at the end of which time the pulse rate had fallen to 72, and the signs of decompensation had practically disappeared. She was given a daily maintenance dose of 1/240 gr.

A. P., a 56 year old white woman, was admitted to the hospital 4/11/35. Three weeks before just after going to bed, she had an attack of wheezing and suffocation which forced her to stand erect for some time in order to get her breath. This was accompanied by very rapid heart action. Following this attack she noticed dyspnea and fatigue when attempting to perform her usual duties, but continued working for one week. During this time her feet became markedly swollen. For the two weeks preceding admission she was unable to do anything, and had to sit propped up most of the time. Her past history was negative except for a "nervous breakdown" three years previously.

On examination it was noted that she was markedly orthopneic and that her neck veins were moderately distended. The apex beat was at the anterior axillary line in the sixth interspace. Rhythm was grossly irregular, apical rate 164, radial 142. The blood pressure 170 systolic and 104 diastolic. There was flatness on percussion over the right lung base, and moist râles on both sides, also râles at left apex. The liver was palpable 3 to 4 cm below the costal margin. There was moderate edema of the lower extremities.

Laboratory. Urine and blood essentially negative. Wassermann 4 plus.

Cardiovascular diagnosis

- A Arteriosclerosis, hypertension
- B Cardiac enlargement, myocardial fibrosis
- C Auricular fibrillation, established
- D Class III

The administration of Verodigen was begun on the day following admission and a total of 12/80 gr given in five days. The patient vomited several times and some of this drug must have been lost. Of this total 3/80 gr was given by rectum. At the end of this time, her apical rate was 104, radial 100, she was much more comfortable and showed signs of diminution in her congestive failure. At this time however she developed a thrombosis of the right femoral artery, which was removed successfully at operation. Two days later however, she suffered a fatal hemorrhage from this region.

C. M., a 48 year old white man, was admitted to the hospital 5/29/35, having had marked dyspnea and orthopnea for the past week. During this time he also had a troublesome cough. Six months previously he had an illness with swelling of the

abdomen, which his family physician said was an 'enlarged liver due to heart disease'

On physical examination, orthopnea was present, but the neck veins were not distended. The apex beat was 3 cm lateral to the mid-clavicular line in the fifth interspace. Rhythm was normal, rate 150. Blood pressure 180 systolic and 112 diastolic. Moist râles were heard over both lung bases. The liver edge was palpable 4 cm below the costal margin but there was no peripheral edema. A seven-foot roentgenogram showed the transverse diameter of the heart to be 17.4 cm, of the chest 31.7 cm.

Laboratory Urine—heavy trace of albumin occasional granular casts. Blood morphology normal. Wassermann negative.

Cardiovascular diagnosis

- A Arteriosclerosis, hypertension
- B Cardiac enlargement
- C Regular sinus rhythm
- D Class II b

The administration of Verodigen was begun the day of admission, and a total of 8/80 gr given in the next three days. During this time the signs of congestive failure cleared rapidly and he was continued on 1/240 gr daily.

J H., a 54 year old white female, was admitted to the hospital 9/28/35. Her present illness began about three months previously, with shortness of breath on exertion. Since that time, she had had symptoms of progressive congestive failure, i.e., dyspnea, orthopnea, attacks of paroxysmal nocturnal dyspnea, edema of lower extremities and swelling of abdomen. She was confined to bed for 10 days. Her past history reveals that she had several attacks of rheumatic fever between the ages of 11 and 20 years. She had had several attacks of congestive failure, all of which had been controlled by digitalis.

On physical examination she showed marked orthopnea and distention of the neck veins. The apex beat was palpable in the fifth interspace 14 cm from the mid-sternal line. There was a diastolic murmur heard best at the apex, followed by a snapping first sound. A loud systolic murmur was also present. The rhythm was grossly irregular, the apical rate being 128, the radial 104. Blood pressure 168 systolic and 105 diastolic. Moist râles were audible over both lower lungs. The liver was enlarged 3 to 4 cm below the costal margin and was quite tender. No evidence of ascites was present. There was pitting edema over the sacral region and the entire lower extremities.

A seven-foot roentgenogram of the chest showed the transverse diameter of the heart to measure 16 cm, of the chest, 26.6 cm.

Laboratory Urine—albumin trace occasional granular casts. Blood slight secondary anemia. Wassermann negative.

Cardiovascular diagnosis

- A Rheumatic fever
- B Cardiac enlargement, mitral stenosis and insufficiency
- C Auricular fibrillation established
- D Class III

Verodigen was begun the day of admission, a total of 8/80 gr being given in three days, at the end of which time all signs of congestive failure had disappeared, and the heart rate had slowed to 80 with no pulse deficit.

Ambulatory patients were followed in the out-patient department of the Medical College of Virginia. None of these cases had been taking digitalis for at least one month prior to starting Verodigen. All of them

SUMMARY OF AMBULATORY PATIENTS FOLLOWED WITH VERODIGEN THERAPY

Case	Age	Sex	Etiologic Classification	Congestive Failure	Blood Pressure	Pulse Rate		Amount Necessary for Digitalization	Maintenance Dose	Period of Observation
						Before	After			
W B	60	M	Arteriosclerosis	++	170/80?	100?	80	6/80 gr	1/240 gr	3 months
J S	56	M	Arteriosclerosis	++	180/120?	130?	90	10/80 gr	1/240 gr	1 month

* These patients succumbed during treatment

had some degree of congestive heart failure. Three patients had fibrillating auricles, the others having regular sinus rhythm. Verodigen was administered orally in either 1/80 or 1/240 grain tablets. Each patient was examined at least once every week.

Initial response to Verodigen was excellent, but frequently after the patients began improving, their apparent well being and alleviation of symptoms caused them to discontinue the routine instructions resulting in a return of congestive failure phenomenon. It may be stated unequivocally that after amounts of Verodigen ranging from 8/80 to 10/80 grains, clinical improvement equalling that obtained with digitalis was noted.

ABSTRACT OF AMBULATORY CASES

W B, a white male, aged 60, entered the out-patient department on August 20, 1935 complaining of shortness of breath and swelling of his ankles for the past three months. Physical examination revealed a dyspneic, aged white male with engorgement of his neck veins. The left border of the heart was 2 cm beyond the left nipple line. The rhythm was totally irregular, apical rate 100. Radial rate 80. Blood pressure 170 systolic and 80 diastolic. Moist râles were present in the bases of both lungs. The liver edge was felt 2 cm below the right costal margin. There was moderate peripheral edema.

Verodigen was given in dosage of 1/80 grain every four hours for six doses, followed by 1/240 grains every night. At the end of seven days, the patient showed remarkable clinical improvement. The venous engorgement had subsided, the moisture in the lung bases was negligible, the heart rate was 84, the radial rate was 80, blood pressure 150 systolic and 70 diastolic, the liver edge could just be palpated, and the peripheral edema had lessened. Three months later, the patient appeared fully compensated taking a daily maintenance dose of Verodigen of 1/240 grain.

Cardiovascular diagnosis

- A Arteriosclerosis, hypertension
- B Cardiac enlargement, myocardial fibrosis
- C Auricular fibrillation, established
- D Class II b

J L S, a colored male, aged 56, entered the out-patient department on September 3, 1935 complaining of shortness of breath, swelling of his ankles, and nocturia over a period of several months.

Physical examination revealed a dyspneic, moderately edematous, colored male with generalized arteriosclerosis. His neck veins were distended. The heart was moderately enlarged, the rhythm was totally irregular, apical rate 130, radial rate 110, blood pressure 180 systolic and 120 diastolic. There was moisture in both lung bases. The liver edge was palpable at the level of the umbilicus. There was moderate pitting peripheral edema.

Verodigen was given in dosage of 1/80 grain every four hours for 10 doses followed by 1/240 grain every night. At the end of 14 days, the patient was improved. The congestive failure phenomena had lessened, the apical rate was 90, the radial rate was 86, a few moist râles were present in the lung bases, there was moderate peripheral edema. One month later the only sign of decompensation was moderate enlargement of the liver and some edema about the ankles. The radial and apical rate remained about 90.

Cardiovascular diagnosis

- A Arteriosclerosis, hypertension
- B Cardiac enlargement
- C Auricular fibrillation, established
- D Class II

C G, a colored male, aged 77, entered the out-patient department on April 25, 1935 complaining of weakness, shortness of breath on exertion, swelling of his ankles, and frequency of urination, over a period of 12 months

Physical examination revealed a dyspneic, old colored male with marked generalized arteriosclerosis. The neck veins were distended. The left border of the heart was in the sixth intercostal space, anterior axillary line. The rhythm was regular. The rate was 110 per minute. There were no murmurs. Blood pressure 185 systolic and 110 diastolic. Moist râles were present in both lung bases. The abdominal wall was edematous. The liver edge was palpated at the level of the umbilicus. There was marked peripheral pitting edema.

Verodigen was given in dosage of 1/80 grain every four hours for five doses followed by 1/240 grain every night. At the end of seven days, the patient was less short of breath, the apical rate was 70 and regular. There was still present some moisture in the lung bases and peripheral edema. Two months later, the patient appeared definitely improved except for continuance of the edema, apical rate 70. No arrhythmia. The patient was not seen afterward but communication with his relatives revealed that he had died of some type of lung infection five months after his first visit.

Cardiovascular diagnosis

- A Arteriosclerosis, hypertension
- B Cardiac enlargement, myocardial fibrosis
- C Regular sinus rhythm
- D Class II b

G J, a colored male, aged 47, entered the out-patient department on April 23, 1935 complaining of a sudden attack of shortness of breath that started 24 hours before admission.

Physical examination revealed a very dyspneic colored male, with moderate distention of his neck veins. The chest was full of coarse, bubbling, moist râles. The left border of the heart was 2 cm beyond the left nipple line in the fifth intercostal space. The rhythm was regular, rate 90, blood pressure 160 systolic and 100 diastolic. There was no definite liver enlargement or peripheral edema.

Verodigen was given in dosage of 1/80 grain every four hours for six doses followed by 1/240 grain every night. At the end of seven days, the patient was clinically improved. The distention of his neck veins and moisture in his chest had disappeared. The heart rate was 84 and regular. He was followed for five months and at no time had any recurrence of dyspnea.

Cardiovascular diagnosis

- A Unknown
- B Cardiac enlargement
- C Regular sinus rhythm
- D Class II b

W G, a colored male, aged 45, entered the out-patient department on April 25, 1935 complaining of shortness of breath and intermittent swelling of his feet and ankles gradually becoming worse in the past nine months.

Physical examination revealed a dyspneic colored male with moderate distention of his neck veins. There were moist râles in both lung bases. The left border of the heart was in the sixth intercostal space at the anterior axillary line. A diastolic

murmur was heard to the left of the sternum in the third intercostal space The rhythm was regular, rate 90 The blood pressure was 150 systolic and 40 diastolic There was a definite Corrigan pulse and Duroziez murmur over the femoral vessels The liver edge was palpable three fingers below the right costal margin There was moderate peripheral pitting edema

Verodigen was given in dosage of 1/80 grain every four hours for six doses followed by 1/240 grain every night After 14 days, the patient could sleep flat in bed, the pulse rate was 90, moisture in the lungs had lessened, the liver edge had receded, the edema of the lower extremities was subsiding He developed a trans-perineal abscess in the following month, which ruptured, and while in a weakened state, the patient contracted a lung infection and succumbed in June 1935

Cardiovascular diagnosis

- A Syphilis
- B Cardiac enlargement, aortic insufficiency
- C Regular sinus rhythm
- D Class II a

W C, a colored male, aged 59, entered the out-patient department on April 23, 1935 complaining of shortness of breath and swelling of his feet for the past three weeks

Physical examination revealed an elderly, anemic, orthopneic colored male with distended neck veins and marked generalized arteriosclerosis Moist râles were found in both lung bases The left border of the heart was in the sixth intercostal space at the anterior axillary line The rhythm was regular, rate 110, blood pressure 200 systolic and 120 diastolic There was an apical systolic murmur The liver edge was felt at the level of the umbilicus The lower extremities were markedly edematous

Verodigen was given in dosage of 1/80 grain every four hours for five doses followed by 1/240 grain every night After seven days, the patient was less breathless, the pulse rate was 84, the blood pressure was 160 systolic and 90 diastolic, the liver edge was felt 2 cm below the right costal margin, the peripheral edema had lessened The patient continued clinically improved until May 21, 1935, when he began having paroxysmal attacks of nocturnal dyspnea On July 1, 1935, he developed an attack of acute pulmonary edema and succumbed

Cardiovascular diagnosis

- A Arteriosclerosis, hypertension
- B Cardiac enlargement, myocardial fibrosis
- C Regular sinus rhythm
- D Class II b

R T, a colored female, aged 46, entered the out-patient department on August 20, 1935 complaining of shortness of breath, paroxysms of coughing, and swelling of the ankles for the past four months

Physical examination revealed an anemic, dyspneic colored female with distended neck veins and moisture in the lung bases The left border of the heart was in the sixth intercostal space 3 cm beyond the nipple line The rhythm was regular, rate 120, blood pressure 180 systolic and 120 diastolic The liver edge could be felt 3 cm below the right costal margin There was moderate peripheral edema

Verodigen was given in dosage of 1/80 grain every four hours for eight doses followed by 1/240 grain every night After seven days, the patient felt better, the pulse rate was 98, the neck veins were not distended, the moisture in the lung bases had lessened, the liver edge could not be felt, blood pressure was 140 systolic and 110 diastolic One month later, the patient continued to improve There was no evidence of congestive failure, blood pressure 150 systolic and 100 diastolic, rate 88

Cardiovascular diagnosis

- A Arteriosclerosis, hypertension
- B Cardiac enlargement
- C Regular sinus rhythm
- D Class II b

E B, a white female, aged 30, entered the out-patient department on May 16, 1935 complaining of shortness of breath associated with swelling of the ankles for the past two years

Physical examination revealed a moderately dyspneic, white female. There was no distention of the neck veins. A few moist râles were heard in both lung bases. The left border of the heart was in the fifth intercostal space just beyond the nipple line. The rhythm was totally irregular, apical rate 120, radial rate 100, blood pressure 170 systolic and 110 diastolic. A diastolic rumble was heard over the mitral area ending in an accentuated first sound. The pulmonic second was accentuated. There was moderate peripheral edema.

Verodigen was given in dosage of 1/80 grain every four hours for five doses followed by 1/240 grain every night. After three weeks, breathlessness had lessened, the apical rate was 104, radial rate 100, blood pressure 160 systolic and 110 diastolic, the pulse was still irregular. The patient left the city after her last visit and has not returned to the clinic.

Cardiovascular diagnosis

- A Rheumatic fever
- B Cardiac enlargement, mitral stenosis
- C Auricular fibrillation
- D Class II a

F M, a white male, aged 48, entered the out-patient department on July 26, 1935 complaining of shortness of breath on exertion and swelling of his ankles for the past three weeks.

Physical examination revealed a well developed white male with no distention of his neck veins. A few moist râles were heard in both lung bases. The left border of the heart was in the fifth intercostal space just beyond the nipple line, rhythm was regular, rate 105, blood pressure 210 systolic and 100 diastolic. The liver edge was not palpable. There was moderate peripheral edema.

Verodigen was given in dosage of 1/80 grain every four hours for ten doses followed by 1/240 grain every night. At the end of 14 days, the patient felt better, the pulse rate was 90, there was no evidence of congestive failure. He has continued feeling well and after two months the blood pressure was 190 systolic and 100 diastolic, the pulse rate 80.

Cardiovascular diagnosis

- A Arteriosclerosis, hypertension
- B Cardiac enlargement
- C Regular sinus rhythm
- D Class II a

H M, a colored male, aged 40, entered the out-patient department on July 30, 1935 complaining of shortness of breath, cough, and swelling of his ankles for the past three months.

Physical examination revealed a dyspneic colored male with distended neck veins and moisture in the lung bases. The left border of the heart was in the fifth intercostal space 4 cm beyond the nipple line. The rhythm was regular, rate 110, blood pressure 180 systolic and 120 diastolic. The liver edge was palpated 3 cm below the right costal margin. There was moderate peripheral edema. The peripheral vessels were markedly sclerosed.

Verodigen was given in dosage of 1/80 grain every four hours for eight doses followed by 1/240 grain every night. After 14 days, the blood pressure was 170 systolic and 100 diastolic, the pulse rate was 90, all of the congestive failure phenomena were subsiding. One month later, the only evidence of cardiac failure was a few moist râles in the lung bases, pulse rate 90.

Cardiovascular diagnosis

- A Arteriosclerosis, hypertension
- B Cardiac enlargement
- C Regular sinus rhythm
- D Class II b

DISCUSSION

The cases in this series were unselected, except that they all showed organic heart disease with congestive failure, and rapid heart rates. None had received digitalis preparations for at least one month previously. Some of them showed auricular fibrillation, others a normal sinus rhythm. The etiology of the heart lesions was in most cases arteriosclerosis with hypertension, in some, syphilis and rheumatic fever, and in others, unknown. In brief, they represent the routine admissions of "congestive heart failure," cases which would ordinarily be treated with digitalis.

It was obvious quite early in our study that the cat unit established experimentally was not an accurate index of clinical dosage. In other words, the dosage determined by biological methods could not be transferred to patients according to the Eggleston method for digitalization. Over and over again, the maximum therapeutic effects were obtained with a dosage far less than that calculated on a basis of the cat unit being 1/80 gr. As nearly as we could judge from a study of our cases, these effects were obtained with approximately 1/3 to 1/2 the calculated dosage. We do not have an entirely satisfactory explanation for this finding. We had expected by analogy with digitalis, that dosages established by biological assay could be used as the basis for human dosage, but we could not confirm this with Verodigen.

It has been contended that the action of Verodigen persists somewhat longer than that of digitalis, an argument which would explain in part the paucity of the required dosage. Since a number of our cases which were followed for several months continued to take only 1/240 gr. of the drug daily, showing neither toxic effects nor return of congestive failure, such a conclusion seems justified. To be able to maintain digitalization with such a small dose (about 1/30 the amount required for digitalization) strongly suggests that the drug is eliminated less rapidly than digitalis. Certainly this was true in the case of biological assays, as shown by Dr. Haag⁵ in his experimental studies.

We found that the total amount of Verodigen necessary for complete digitalization varied from 6/80 to 10/80 gr. Those patients requiring the larger doses as a general rule weighed more and required a longer period of time for digitalization. These figures approximate those determined by

Stroud et al From such findings, we accepted arbitrarily 1/240 gr as a daily maintenance dose It was impossible for us to accurately "titrate" human beings, with a class of patients who could remain in the hospital but a limited time The problem was rendered more difficult by having as criteria symptoms and signs that do not lend themselves to exact measurement Suffice it to say that those of the group who have been followed over a period of months on such a dosage, showed no evidence of toxic reactions or return of decompensation

As was mentioned before, the cases in this group were similar to those in whom we would ordinarily have used digitalis It seems justifiable to say, as a general statement, that the effects produced by Verodigen are qualitatively similar in every respect to those obtained with digitalis When we analyze the various subjective and objective results in these patients, the truth of such a statement is evident All of our cases were in congestive failure, the result of heart disease All showed both subjective and objective evidence of cardiac decompensation Subjective improvement was shown by the disappearance of dyspnea, orthopnea and other distressing symptoms which ordinarily accompany congestive failure An analysis of the objective measurements revealed the same improvement, specifically, a slowing of heart rate, together with a decrease in pulse deficit in those patients having auricular fibrillation, an increase in vital lung capacity, disappearance of râles, ascites and edema, diminution in the size in the liver, and finally, an increased output of urine It may well be argued that some of these results would have been obtained simply by rest in bed It must be remembered, however, that the majority of these patients had been confined to bed at home without improvement, and further, that drugs of the digitalis group have been shown to be necessary in such cases

When we come to compare the effects of the drug quantitatively with those of digitalis, there are certain apparent differences It has been stated by some clinicians that Verodigen produces a therapeutic digitalis action more rapidly than other digitalis preparations It is true that some of our cases showed excellent therapeutic effects as early as the second or third day, but others required a longer time for complete digitalization It does seem probable that Verodigen is rapidly and completely absorbed, when we consider the small dose actually required as compared with the dose calculated from biological assay

Regarding the toxic effects of Verodigen, we have had little experience, for seldom was it necessary to force the drug to such a point However, we have gained the impression that it is very well borne by the gastrointestinal tract, for it produced no gastric symptoms even in those cases where it was given in overdosages For example, two of our cases developed extrasystoles after taking large doses of the drug, but showed no loss of appetite or nausea Another patient, who is not included in this group because his condition was found on further study to be primarily

nephritic, received 1/4 gr Verodigen before developing nausea, even though he did not vomit and continued to have a good appetite. About the time that nausea appeared, he developed a partial heart block. We had given him this large amount of the drug because he was one of the first cases we studied, and we expected that such an amount would be necessary for digitalization. Another patient, a woman weighing 130 lbs, whom we studied early in our series and who was proved later to have malignant nephrosclerosis, received 1/4 gr over a period of 12 days, only becoming nauseated toward the end, but not vomiting. About the time that nausea appeared, she developed a coupled rhythm. We mention these two cases to support the contention that large amounts of Verodigen may be taken without producing severe gastrointestinal symptoms. It will be noted from a study of our case records that two of our patients did show vomiting. This was early in the course of administration, however, and ceased even though the drug was continued in the same dosages.

Practically all of these cases had seven-foot roentgenograms made of the chest on admission to the hospital. This was repeated in about half of the cases after we felt that full digitalization had been secured. Invariably the transverse diameter of the heart showed a decrease of 1 to 4 cm in relation to the diameter of the chest wall.

Electrocardiograms were made on all cases on admission to the hospital, and several times thereafter. We were unable to demonstrate any constant change in the T-wave or S-T interval following Verodigen, except in one case (mentioned above, but not reported in this series) who received 1/4 gr of the drug over a period of 12 days, toward the end of which time he showed a prolongation of the P-R interval, depression of the T-wave, and finally a partial block. We were not surprised at the absence of electrocardiographic changes, for they have been observed infrequently in our experience during the routine use of digitals.

CONCLUSIONS

From our clinical studies it appears that Verodigen exerts the same qualitative therapeutic effects as digitalis, and provokes the same symptoms when given in overdoses.

Our observations are in conformity with previous reports^{4,6} which definitely indicate that the "biological unit" of digitalis is not always an accurate criterion of clinical dosage. The absorption, potency, and rate of elimination are of equal importance.

In the case of Verodigen the relation of "therapeutic unit" to "biological unit" would seem to indicate a persistence of action which is necessary for a prolonged and uniform digitalis effect.

From our studies so far, we have gained the impression that it is very well tolerated by the gastrointestinal tract, and does not produce gastric disturbances even when administered in moderate overdosage.

Following the oral administration of Verodigen excellent therapeutic effects were noted in many cases as early as the second or third day, although others required a longer time for digitalization

A COMPARISON OF THE SYMPTOMS, PHYSICAL AND LABORATORY FINDINGS OF MYXEDEMA AND PERNICIOUS ANEMIA, WITH A REPORT OF THREE CASES¹

By JAMES A. GREENE, M.D., *Iowa City, Iowa*

THE clinical manifestations of myxedema and pernicious anemia are sufficiently alike to account for the fact that the former disease is frequently mistaken for the latter. The similarities and differences of the two diseases, however, have not been emphasized. The purpose of this report is (1) to compare the clinical manifestations of the two diseases, (2) to present two cases of myxedema in which it was difficult to exclude pernicious anemia, and (3) to report another case of pernicious anemia and myxedema. The data were obtained from the records of 100 unselected cases of pernicious anemia and 33 cases of myxedema.

Symptomatology Both diseases are chronic as a rule, with varying degrees of debility. In fact, the debility may be the only presenting symptom. The occurrence of the usual symptoms referable to the hematopoietic, circulatory, gastro-enteric, and nervous systems in the two diseases is listed in table 1.

TABLE I

Occurrence of symptoms referable to hematopoietic, circulatory, gastro-enteric and nervous systems in pernicious anemia and myxedema

	Pernicious Anemia			Myxedema		
	Pos	Neg	Not Stated	Pos	Neg	Not Stated
Pallor or anemia	81	8	11	18	6	9

From the Department of Internal Medicine, State University of Iowa Medical School

tongue and jaundice, which are common in pernicious anemia, may also occur in myxedema, and intolerance to cold and slowness of muscular and mental activity which are common in the latter disease may be present in the former. Paresthesia, which is considered to be one of the cardinal symptoms of pernicious anemia because of its frequency, occurred in more than one-third of the cases of myxedema.

Physical Findings The general appearance of the patients may be similar. Pallor is prominent in both diseases. Myxedematous deposits do not occur in pernicious anemia but they may be slight and easily overlooked in patients with myxedema. The brownish pigmentation of the skin in myxedema may suggest an icteric tint but the sclerae are clear. While five of the patients gave a history of jaundice, it was not present at the time of examination. The atrophic tongue found in pernicious anemia was observed in three cases of myxedema.

Paralysis	absent 5	present 0	95	absent 16	present 1	16

* Alternating motion rate

It is to be noted from table 2 that the neurological changes common to pernicious anemia may also be observed in myxedema. The eight patients with myxedema who showed partial or complete pallanesthesia were less than 50 years of age, therefore the pallanesthesia which is frequently observed in patients over 55 years of age was not a factor. A decrease or loss of the sensations of two-point discrimination and position is rare in myxedema, while it is common in pernicious anemia. On the other hand, a decrease of the alternating motion rate of the tongue or hands is commonly encountered in myxedema but rarely observed in pernicious anemia. Ataxia may be present in both conditions and varies from slight unsteadiness upon turning quickly to complete abasia. An extreme stagger was observed in two patients with myxedema and in two instances abasia was present.

Laboratory Findings The anemia of myxedema usually has a color

index below 1.0 but in 12 of the cases studied there was an anemia with a color index of 1.0 or above. The red blood cells did not show the marked variation in size and shape that is seen in pernicious anemia and true macrocytes are rarely, if ever, present.

Achlorhydria is perhaps one of the most constant laboratory findings in Addisonian anemia, yet it occurred in five of 14 cases of myxedema. The blood bilirubin (van den Bergh) is usually elevated in pernicious anemia and this was observed in 5 of 11 cases of myxedema. The basal metabolism usually is of value in differentiation of the two diseases, in that it is normal or slightly elevated in pernicious anemia and low in myxedema. A low basal metabolic rate, however, may occur in pernicious anemia during and following the reticulocyte crisis. Alt¹ reported one case in which it was minus 28 per cent and Baldrige and Bare² recorded one instance in which the basal metabolic rate fell to minus 20 per cent.

Cases Difficult to Differentiate In spite of the fact that the clinical picture of the two diseases may be similar, the differentiation is usually not difficult. The difficulties that arise occasionally are illustrated in the following cases.

CASE REPORTS

Case 1 A white married female, aged 55, entered the Indianapolis City Hospital complaining of weakness and numbness of the legs. She had always enjoyed good health except for nervousness and vague gastrointestinal symptoms, until four years before the first admission to the hospital at which time weakness and paresthesias were noted. The symptoms decreased two years later following a blood transfusion but the weakness returned, the paresthesia extended to the hips, and vomiting, diarrhea and slight jaundice were also present at the time of the first admission. There was impairment of pressure, thermal, tactile and pain sensations over the legs. The red blood count was 1,880,000, hemoglobin 38 per cent, white blood count 11,900, and the blood smear showed marked anisocytosis and an occasional nucleated erythrocyte. Marked clinical improvement followed two blood transfusions, but during the next seven years, until readmission to the hospital the following symptoms were noted: A gain in body weight, dryness of the skin, loss of hair, absence of sweating, intolerance to cold, swelling of the hands and feet, decreased mental activity, loss of memory, ataxia and a marked staggering gait. The weakness and paresthesia became increased during the last three years of this period and she was referred to the hospital with a diagnosis of pernicious anemia, but upon examination she was found to have myxedema. The reflexes were sluggish and the lower legs were markedly hyperaphic. Pallanesthesia was present to the twelfth dorsal vertebra and the position and thermal senses were decreased over the legs. A marked stagger was present and the Romberg test was positive. The red blood count was 4,270,000, hemoglobin 86 per cent, and the blood smear was normal. Achlorhydria was present, even after histamine. The basal metabolic rate was 33 per cent below normal.

The myxedema subsided following the administration of desiccated thyroid and the neurological condition improved. Five months later the pallanesthesia and Romberg test were unchanged but marked improvement was noted in the gait and paresthesia.

Case 2 A white married female, aged 57, entered the University Hospital complaining of weakness, inability to walk, and pain in the legs. The patient was well until eight years before admission when she noted ataxia, paresthesia, sore tongue

and pallor. The physician consulted at that time made a diagnosis of a "posterior cord lesion." The red blood count was 2,400,000, hemoglobin 50 per cent, and there was no free hydrochloric acid in the gastric juice. The blood Wassermann was 4 plus. She received antisyphilitic treatment with mercury, bismuth and iodides for six months, with some general improvement. Three years later the pallor increased, jaundice developed and the patient suddenly became unable to walk. Within a few minutes she became unconscious and was taken to a hospital where the red blood count was 1,800,000 and hemoglobin 55 per cent. Achlorhydria was again found and prompt improvement followed liver and liver extract therapy. After two months the red blood count was 4,420,000 and hemoglobin 75 per cent, but reticulocyte counts and a basal metabolic rate were not obtained. She continued to improve but the abasia persisted, and dryness of the skin, loss of hair and gain in weight were noted during the three-year period prior to admission. Liver and liver extract were omitted for six months, she gradually became weaker, and was referred to the hospital with the diagnosis of pernicious anemia.

Upon examination she was found to have myxedema and the following neurological findings: A positive Babinski reflex and a decrease of the sensations of position, two-point discrimination and pallesthesia of the lower legs.

The red blood count was 3,140,000 and hemoglobin 75 per cent. Achlorhydria was present even after histamine. The blood bilirubin was normal and the basal metabolic rate was 48 per cent below normal.

The reticulocyte count, red blood count, and hemoglobin did not change following adequate amounts of liver extract before and after the myxedema had been controlled with desiccated thyroid gland. Nine months later the neurological symptoms and findings were unchanged and the red blood count was 4,600,000 and hemoglobin 68 per cent.

Although 20 months later the neurological symptoms and findings were unchanged, she was able to walk with the assistance of a cane. The erythrocyte count was 4.4 million and hemoglobin 82 per cent. The intrinsic factor was found to be absent from gastric juice when analyzed by the method described by Castle³. The negative result in this case may have been due in part to the small amount of gastric juice obtained, which varied from 50 to 150 cc daily. The intrinsic factor, however, was present in comparable amounts of gastric juice obtained from another patient with myxedema who had an achlorhydria without an anemia.

It is difficult to exclude pernicious anemia in the two cases. The normal blood count in the first case is against pernicious anemia, yet spontaneous remissions occur. The failure of the second case to respond to adequate liver therapy before and after the myxedema had been controlled is inconsistent with pernicious anemia, yet there was a primary anemia, a history of definite response following liver and liver extract therapy and the intrinsic factor was absent from the gastric secretions. Cases of co-existing pernicious anemia and myxedema reported by Sturgis and Isaacs⁴ and Means, Lerman and Castle⁵ had a hematopoietic response following liver extract. However, the anemia of myxedema did not respond to liver extract in the cases studied by Baldrige and Greene⁶ and Lerman and Means.⁷

The presence of subacute combined sclerosis in both cases adds to the difficulty, since myxedema is not listed as one of the etiological factors and some neurologists think that it occurs only in pernicious anemia. A review of the neurological conditions that may occur in myxedema by Mussio-Fournier⁸ did not include subacute combined sclerosis. Briggs⁹ observed

two cases of anemia with myxedema and evidence of combined systemic disease, and thought that they were not true pernicious anemia. Both cases were not improved with thyroid therapy and terminated fatally. Lissner and Anderson¹⁰ insinuate that the presence of cord lesions is of grave prognosis in myxedema, but both of my patients responded to thyroid in the usual manner.

Myxedema and pernicious anemia were the only possible etiological factors for the subacute combined sclerosis in my first case, while syphilis was a possibility in the second case. But negative blood and spinal fluid Wassermanns and normal spinal fluid cell count and globulin during the time the patient was in the University Hospital and the absence of other evidence of syphilis, are strong evidence against syphilis as the etiological agent. If subacute combined sclerosis does occur in myxedema, it adds further to the difficulty in differentiation of pernicious anemia and myxedema in some patients.

The following case is reported as an instance of the coincidence of both pernicious anemia and myxedema.

Case 3 A white male, aged 44, entered the University Hospital complaining of weakness, pain in the right chest, and anemia. He had always been well until 1926 when weakness and jaundice were noted. He went to a well known clinic in June 1927, and was told he had pernicious anemia. The red blood count was 1,610,000 and hemoglobin 33 per cent. He was given a liver diet and the red blood count increased to 2,910,000 and the hemoglobin to 60 per cent. A mild subacute combined sclerosis was present at that time. The patient continued to take a liver diet and liver extract intermittently and felt fairly well. During the two or three years before admission to the University Hospital paresthesia became increased and the following symptoms appeared: Slight dyspnea upon exertion, difficulty of hearing, slowness of speech, loss of hair, thickness of the tongue, slow mental reaction, poor memory and sensitiveness to cold. Seven weeks before admission he developed pneumonia which was complicated by pleural effusion. Following this the symptoms were aggravated and he noted awkwardness in buttoning his clothes. The patient was sent to the hospital with the diagnosis of pernicious anemia and pleural effusion, but upon examination he was found to have pleural effusion and myxedema. Paresthesia and absence of the two-point discrimination were found over the lower legs but the position sense was normal. The red blood count was 4,020,000, hemoglobin 58 per cent, and hematocrit 35.5 per cent. The red blood cells in the smear were deeply stained but polychromasia was absent. The size and shape of the cells did not show the variation anticipated for pernicious anemia. A majority of the polymorphonuclear cells contained several lobes. The blood bilirubin (van den Bergh) was normal and free hydrochloric acid was absent from the stomach. The basal metabolic rate was 44 per cent below normal.

With the slight anemia it was felt that the pernicious anemia was not of consequence in the patient's condition and liver extract and desiccated thyroid were given. Prompt improvement in the patient's condition occurred and the red blood count increased to 4,490,000 after one month.

In the cases of coexistent myxedema and pernicious anemia reported by Means, Lerman and Castle⁵ the pernicious anemia antedated the myxedema. This was also true in the case just reported. It must be said that if these

instances of the simultaneous existence of the two conditions are evidence of some relationship between them the nature of this relationship remains entirely obscure

SUMMARY

Although myxedema and pernicious anemia are as a rule easily differentiated, there may be no distinctive features in the history, physical or laboratory findings. The two diseases are not likely to be confused if myxedema is considered in the differential diagnosis of pernicious anemia. The neurological findings, blood smear, and basal metabolic rate are of the greatest value in the difficult cases. Both diseases may be present and a therapeutic test with liver extract may be necessary to ascertain the presence or absence of pernicious anemia, yet a negative response in the presence of subacute combined sclerosis leaves the diagnosis uncertain.

CONTROL OF THE TOBACCO HABIT¹

By JOHN L. DORSEY, M.D., F.A.C.P., *Baltimore, Maryland*

THE physician is frequently called upon to plan a regimen for the patient under his care where it is more or less apparent that some restriction in the use of tobacco is desirable. The indications for such limitation are not clear-cut because the effects of nicotine as a chronic poison to those who habitually smoke to excess are by no means obvious, and are certainly subject to considerable individual variation. Whether nicotine plays a definite part in various forms of vascular disturbance may be open to some discussion, but it is within the practitioner's routine experience to observe that appetite is reduced by smoking, that the sense of general well-being is sometimes adversely affected, that various lesser disturbances (cough, palpitation, nausea, fetor oris, vague indigestion) are at times associated with excessive use of tobacco. Reference to current medical literature shows that the consequences of the abuse of tobacco are being recognized. In the past three years the ill effects of nicotine have been discussed in connection with such varied subjects as peripheral vascular disease, organic and functional diseases of the stomach, pregnancy, headache, hyperglycemia, rhinitis, hypertension, asthma, cirrhosis of the liver, deafness, amblyopia, ether anesthesia, and others. This in face of an endless barrage of propaganda laid down by the tobacco companies in the form of attractive advertising and irresponsible physiology. Some of our "best people" live in a world where one smokes all day long "for digestion's sake," where certain brands of tobacco fail to "get the wind," and are exclusively used by our various champions, where one's private pH is puffed up or down by change in manufacturer—or so at least, according to the back page of almost any magazine. Even our medical journals now carry cigarette advertisements with a scientific flavor. The whole medical directory receives a carton in its mail and any physician who smokes a pack or two is qualified to render a scientist's opinion on the superior merits of the enclosed brand.

It would seem to be accepted that the ill effects of tobacco, whether taken as smoke or otherwise, are largely associated with the nicotine present in the leaf. That a very appreciable amount of this alkaloid is absorbed by the heavy smoker has been demonstrated. The plants from various parts of the world vary widely in their nicotine content, most of our native tobaccos containing a high percentage of the alkaloid. It is also of interest to note that the smoker who does not inhale will absorb only a third less nicotine than the more orthodox smoker, saliva being a solvent for this alkaloid.

If we accept the fact that the use of tobacco in its various preparations is a form of drug addiction, even though a pleasant one not affecting

* Received for publication April 30, 1936

criminal statistics, we can more readily help our patient when he finds that his problem has gotten out of hand. Merely to advise that smoking be discontinued is usually futile. The real addict, the smoker of 20 to 50 cigarettes a day, cannot lay aside the habit of years with an easy nonchalance. He has ahead of him wretched days of withdrawal symptoms which will usually end with surrender to the habit which is more deeply rooted than one cares to admit. The moral catastrophe is very like the alcoholic's. Ingenuity is exercised in discovering reasons to escape from the new resolution. In the end, most say in their desperation that no theoretical harm which tobacco might do is enough to make them endure the wretched state of their person, and a return to the old habit very quickly finds them back at the former level of consumption. Marked limitation in tobacco well below a previously established quantity seems more difficult than complete abstinence. In addition to the nervous symptoms which follow withdrawal, the mechanical aspect of smoking or chewing plays some part. After a man has lit a cigar, cigarette or pipe after every meal for many years he will at first be at a loss what to do with his hands at such times. Likewise the confirmed cigarette smoker wants a cigarette between fingers or lips when under any tension.

The first requisite in the cure is a patient who *wants* to stop the use of tobacco in any form. The reasons may be medical, financial, aesthetic, or otherwise, but the determination to discontinue must be there if we are to get any permanent result with the nicotineist—as is true for all addictions.

In an attempt to find some medicinal preparation which would lessen the deprivation symptoms when tobacco is cut off, trial was made of lobelia, which closely resembles nicotine in its effects upon the nervous system.

Lobelia, or Indian Tobacco, the leaves and tops of *L. inflata*, a common wild flower with a blue blossom, was used for smoking and chewing by the American Indians in place of, or mixed with, tobacco. In 1813 Cutler wrote of the use of lobelia in asthma and other spasmodic respiratory conditions. Since then it has been in vaying favor for its local and systemic actions, used chiefly by the Eclectic school. Recently its importance has been as a respiratory stimulant.

Lobelia has been shown to contain five alkaloids, chief of which is lobeline, $C_{22}H_{27}NO_2$. Lobeline exerts almost the same effects as nicotine. There is caused a brief stimulation of the motor centers in the spinal cord and medulla. This stimulation is soon followed by depression, and later paralysis with large doses. The feature of the action of the drug is the stimulation of the motor nerve endings in the involuntary muscles. The symptoms of poisoning resemble those of nicotine: nausea, giddiness, faintness, vomiting, cold sweats. The use of nicotine leads to some tolerance for lobeline.

The usual plan has been to have the patient smoke as is his wont on the first day until the mid-day meal is eaten. All use of tobacco is then

abruptly stopped. The first dose of lobeline sulphate, 0.008 gm (1/8 gr.), is given by mouth in capsule form immediately after the meal. The drug is then further used in the same dosage as the patient may feel the urge to smoke. It has not been found necessary to use over 18 doses in 24 hours and often three or four have been sufficient. The patient decides when a dose is necessary and for how many days he needs this form of substitution therapy. A week of gradually lessening use of lobeline has been ample in most cases, with a few capsules on hand to meet any sudden recrudescence of the former urge. It seems less distressing to start this treatment on a day of rest rather than when the patient is under the pressure of his usual activities.

After the first several doses of lobeline the desire to smoke grows less and less insistent. The hunger returns in waves which are progressively easier to put off without the use of the Indian Tobacco. For a day or two there may be some nausea, a metallic taste, and an uncertain feeling of malaise, but no more unpleasant symptoms have been encountered. As with tobacco, nausea protects against gross over-dosage. The first subjective improvement noted has been a marked increase in the acuity of the olfactory and gustatory senses. One man who had smoked 40 cigarettes daily for at least 15 years said on his third day of lobeline that he was tasting and smelling things which he had almost forgotten. A disconcerting revelation which this latter sense quickly reveals is that the non-smoker suffers in the near presence of the smoker, having lost his protective adaptation. Appetite shows prompt improvement, sometimes to a marked degree, and this can be taken advantage of at once. Nervous, undernourished young women in particular are sometimes seen to undergo a renaissance when tobacco is put away. Likewise, the tense, active, tired man often improves his state of health markedly by interruption of this habit. The irritation of the smoke in the upper air passages is an effect which leaves behind no regrets at its passing. The nasopharynx seems surprisingly clear when freed of this foreign matter. The chronically coated tongue of the heavy smoker loses its covering. Better "wind" is regularly observed. The most gratifying improvement is the increased endurance and the improved sense of well-being which have been reported by former addicts. A definite hypothyroidism developed in two patients about six weeks after tobacco was stopped. It is of interest to consider whether there was any causal relationship here. Another man who had suffered with cold hands and feet for years during the winter, found himself free of this complaint in his first winter without tobacco. Two men use lobeline to restrain their desire to smoke when they must be for some time in places where this practice is prohibited. A "hard night" is distinctly less "hard" when tobacco is omitted. It must, of course, be recognized that excessive use of tobacco may be a result of nervous irritability as well as its cause. Apparently the results have been the same with either sex.

This general plan has been followed out over a period of eight months with a series of patients who had previously tried stopping gradually or abruptly but had all gone back to the pleasant vice. The results have been encouraging. In the great majority of instances it has been stated that there was no comparison between the uneasiness of stopping without lobeline and when this drug is used as a buffer. Once the acute discomforts are passed, the alternate drug is omitted, and then it is a question for the patient to decide whether he thinks it worth while to "stay stopped." He will frequently regret the passing of his former solace but will not again suffer severe pangs for the want of it.

The lobeline can be expected to reduce the misery of deprivation to within relatively easy limits. It is to dull the acute symptoms of withdrawal that the drug is used. After this stage is passed, it is comparatively easy to abstain from tobacco if there is determination to do so.

STUDIES OF THE NITROGEN AND SULPHUR METABOLISM IN A CASE OF CYSTINURIA¹

By G P GRABFIELD, F A C P, and B PRESCOTT, *Boston, Massachusetts*

SINCE the introduction of satisfactory methods of studying the sulphur partition, a number of cases of cystinuria have been studied without, however, providing a basis for an adequate explanation of the condition. Excellent reviews¹ of the cases so far studied have been published. The metabolic data are confusing and contradictory^{2,3}

Our purpose was to study the effects of diets high and low in sulphur on the cystine excretion in a patient with cystinuria. As will be seen this could be accomplished only indirectly. On account of the intimate connection between the nitrogen and sulphur metabolism, it was desirable to devise a diet or rather a set of diets in which the nitrogen intake would be constant while the sulphur intake varied. Such a diet would also eliminate the influence of the specific dynamic action reported by Lewis⁴. He found that cystine excretion varied with the total protein of the diet rather than with its cystine content.

To this end we used gelatin as the chief source of dietary protein in our test diets. Such a diet contains a minimal amount of cystine sulphur and is low in total sulphur content. From a practical point of view if the cystine output can be reduced, calculus formation should be delayed.

Our patient was a married woman, aged 35, who had had her first attack of renal colic in the winter of 1928-29. It was not until December 1933 that she was operated upon at the Massachusetts General Hospital and four calculi were removed from the left renal pelvis. They were analyzed by Dr Fuller Albright and found to be pure cystine, and we are indebted to him for the opportunity of studying this patient. After removal of the stone, the urinary infection cleared up but cystine crystals continued to be present in her urine. She entered the Peter Bent Brigham Hospital for metabolic study in April 1934. At that time she was symptom-free except for marked hysteria, which is recorded as a usual symptom in a large number of these patients. Indeed this was such a prominent feature that it prevented the blood analysis which we had planned. Usual examinations revealed no deviation from the normal except for the presence of cystine crystals and a positive Millon reaction in the urine suggesting the presence of tyrosine. Her family history presented no evidence of the hereditary factor which has been noted in one-third of the reported cases. We had the opportunity to examine the urines of only two siblings and the patient's son, all of which were negative for cystine. No arthritic tendencies were re-

* Received for publication July 3, 1936

From the Medical Clinic of the Peter Bent Brigham Hospital

This study was aided by a grant from the Proctor Fund for the study of Chronic Diseases, of Harvard University

pointed out were joint deposits found. This patient, therefore, showed calculus formation and markedly hysterical temperament, but failed to show athritic tendencies or hereditary factors, these four being the usually described clinical features associated with this anomaly. During her stay in the hospital the quantity of cystine crystals varied greatly, as has been the case with all patients observed.

The procedure was that usually employed in metabolic experiments. The diet was calculated from standard tables and duplicate diets prepared, one eaten by the patient, the other analyzed for nitrogen and sulphur. In order to insure constancy, the same foods were eaten every day with particular care to provide the same cuts of meat and parts of vegetables. Table 6 outlines the basic diet and the test diet in which gelatin was substituted as almost the sole source of protein. Urine was analyzed for the various sulphur fractions⁶ and certain nitrogenous elements,⁷ stools for total nitrogen and total sulphur.

In our hands the Looney cystine method⁸ was entirely unreliable, often giving results for cystine sulphur higher than the organic sulphur (cf. table 5). Similar results with this method were obtained by Lewis and Lough and indeed by Looney, Berglund and Graves themselves. Through the kindness of Professor Lewis,⁹ but too late for use throughout this study, we were enabled to use his modification of Lugg's¹⁰ simplification of the highly specific Sullivan reaction. In period 6 of the study (table 5) it was found that the figures of the Looney method and this new method checked very closely indicating that perhaps 50 per cent to 70 per cent of the neutral sulphur in our patient consisted of cystine. During this period (the last) the figures by the Looney method were reasonable in relation to the total organic sulphur, whereas in other periods they were obviously too high. Consequently, our results are based on the figures for neutral sulphur.

TABLE I

Showing the sulphur metabolism during the first experiment. All figures represent 24 hour excretion in milligrams. The percentage of the total sulphur is indicated for the various fractions of the urinary sulphur partition.

Period	Time	Total S	Total SO ₄			Inorganic SO ₄		Ethereal SO ₄		Neutral S		Stool S	S Balance
Number	Days	Mg	Mg	%	Mg	%	Mg	%	Mg	%	Mg	Mg	
I Control	4	634	520	82	473	75	48	7	109	18	92	+ 1	
II Gelatin	4	434	373	86	337	78	36	8	61	14	35	-42	
III Control	4	486	403	83	310	64	99	19	81	17	150	+ 7	

We carried out two experiments on this patient. In the first we substituted gelatin for almost all the protein in her mixed control diet. Recognizing that gelatin is incomplete in other respects than cystine, we added

tyrosine and tryptophane to the gelatin diet in the second experiment. This was especially important in that our patient in all probability had a tyrosinuria also. The feeding of tyrosine in a patient with tyrosinuria and cystinuria might throw some light on the suggested anomaly of the intermediary metabolism said to be concerned in cystinuria.

The first table shows a summary of the details of the sulphur excretion in the first experiment. The so-called organic sulphur fraction of the urine contains the excreted cystine. The normal source of this fraction and its constituents are largely unknown. It behaves much like creatinine in the nitrogen partition and is very constant and unaffected by ordinary fluctuations in food intake. It represents on the average 5 to 10 per cent of the total sulphur excretion at ordinary dietary levels. This patient was on a diet of 58 grams of protein and at this level the organic sulphur should be normally less than 10 per cent of the total urinary sulphur. It may be seen that the organic sulphur fraction was high in all three periods but is diminished both absolutely and relatively when gelatin is the principal source of protein in the diet. Not much change is evident in the other sulphur fractions. There is a noteworthy reduction of the stool sulphur during gelatin feeding. Whether this represents altered digestive processes, as is suggested by the fall in ethereal sulphates, or merely an effort to remain in sulphur balance, is not clear. In table 2 are shown the corresponding details

TABLE II

Showing the nitrogen metabolism corresponding to the sulphur figures recorded in table 1. The period numbers correspond in the two tables. Percentages are of total urinary nitrogen.

Period	Volume	Total N	Urea N		Am Ac N		Creatinine N		Fecal N	N Balance
	c c	gm	gm	%	mg	%	mg	%	gm	gm
I	786	8.0	5.5	69	130	1.6	283	3.5	1.4	- 1
II	1041	9.8	6.3	64	178	1.8	276	2.8	.5	- 9
III	736	7.5	5.7	76	134	1.8	280	3.7	1.5	- 2

of the nitrogen excretion during the first experiment. This patient is in nitrogen equilibrium except during the gelatin period and in this respect behaves normally.^{12 13} The urinary amino acid nitrogen showed a distinct rise in the gelatin period though the concentration is unchanged, owing to a diuresis which in our experience always accompanies the substitution of gelatin as the sole source of protein.

In the second experiment we added tyrosine (1.5) and tryptophane (1.0) to the gelatin diet. In comparing the output during this period with that on the diet containing gelatin alone, it is evident that the addition of these amino acids to the incomplete gelatin reduces both the negative sulphur balance (table 3) and the negative nitrogen balance (table 4). This reduction

TABLE III

Showing the sulphur metabolism during the second experiment All figures represent 24 hour excretion in milligrams The percentage of the total sulphur is indicated for the various fractions of the urinary sulphur partition

Period	Time	Total S	Total SO ₄			Inorganic SO ₄		Ethereal SO ₄		Neutral S		Stool S	S Balance
Number	Days	Mg	Mg	%	Mg	%	Mg	%	Mg	%	Mg	Mg

in negative nitrogen balance cannot be accounted for by the addition of 270 mg of amino acid nitrogen alone At the same time, it will be seen that the amino acid excretion rises higher than in the previous gelatin period indicating that some of the ingested amino acid is excreted unchanged or that the ingestion of amino acids in some other way causes an increase in the amino nitrogen in the urine This period is the only one in which the

TABLE IV

Showing the nitrogen metabolism corresponding to the sulphur figures recorded in table 3 The period numbers correspond in the two tables Percentages are of total urinary nitrogen

Period	Volume	Total N	Urea N		Am Ac N		Creatinine N		Fecal N	N Balance
Number	c c	gm	gm	%	mg	%	mg	%	gm	gm
IV	862	8.7	5.6	64	122	1.4	290	3.3	1.3	- 3
V	851	9.3	6.2	67	250	2.7	280	3.0	1.1	- 5
VI	803	6.8	4.5	66	159	2.3	280	4.1	1.9	+ 5

amino acid excretion is above the usually stated normal Such figures are 1 to 2 per cent ³ of the total nitrogen or a concentration of less than 20 mg per 100 c c ¹³ In table 4 it will be seen that the amino acid excretion exceeds 2 per cent of the total nitrogen in the last two periods, but in the last period the concentration is just below 20 mg per 100 c c However, the excretion in the fifth period is increased over the normal by both the criteria mentioned In period 2, when gelatin alone was fed, the amino acid nitrogen excretion rose from 130 to 178 mg During period 5 the amino nitrogen excretion was 250 mg Thus the addition of 270 mg of amino acid nitrogen to the gelatin diet was followed by an increase of 72 mg in the urinary excretion Since the after period showed a somewhat higher figure than before we may add 25 mg to this figure as total extra amino nitrogen excretion after feeding amino acids This figure is 20 mg less than the

tyrosine nitrogen fed and suggests that some of the tyrosine must have been utilized even if all of the tryptophane was. However, we can say with certainty that about three-fifths of the amino acid nitrogen ingested by this

TABLE V

Showing relation between cystine excretion determined by Looney method and related urinary constituents in the two experiments. It will be seen that this method yielded results that were obviously too high in the first experiment though they closely paralleled the neutral sulphur. The periods are numbered to correspond with the other tables.

Period	Neutral S Mg	Cystine S Mg	$\frac{\text{Cystine S}}{\text{Neutral S}}$ %	Amino Ac N Mg	Cystine N Mg	$\frac{\text{Cystine N}}{\text{Amino N}}$ %
I	109	142	130	130	63	48
II	61	111	182	178	49	28
III	81	125	155	134	56	42

V	67	66	98	250	29	12
VI	195	112	57	159	50	31

patient was deaminized. It is evident, therefore, that this patient with cystinuria and tyrosinuria can utilize only part of ingested amino acids other than cystine. The normal organism excretes all ingested amino acid as urea, and Lichtman¹⁴ has shown that even most patients with hepatic disease can oxidize two grams of tyrosine fed by mouth.

TABLE VI

A tabular view of the diets fed as calculated from standard diet tables. In the other tables the nitrogen and sulphur balance is figured on the results of actual analysis of the food eaten.

	"Normal" gm	"Test" gm
Protein	58	58 (45 gelatin)
Carbohydrate	173	132
Fat	125	118
Calories	2049	1831
Water (including that in food)	1809	1838
Sulphur	0.69	0.14
NaCl	1.57	0.75
Added NaCl	2.00	3.00
Total NaCl	3.57	3.75

In both our experiments this increase in amino acid nitrogen excretion was accompanied by a diminution of cystine nitrogen as estimated from the organic sulphur excretion. However, the increased amino acid excretion might conceivably be due to failure of a deamination in the kidney, as

Krebs¹⁵ has shown that isolated renal tissue possesses powerful deaminizing powers and has postulated that ammonia formation observed by Nash and Benedict¹⁶ is a result of this deamination and is regulated by the neutrality needs of the organism. Unfortunately such studies were not carried out on this patient.

These experiments do not support the idea that cystine output is solely dependent upon the specific dynamic action of protein. These studies may be interpreted as in accord with the hypothesis that this anomaly is concerned with the intermediary metabolism.

In view of the diminution of organic sulphur excretion when gelatin is fed, it seems logical to conclude that the liberal use of gelatin in the diets of these patients might be a useful therapeutic procedure.

SUMMARY

- 1 A case of cystinuria was studied metabolically on high and low sulphur diets using gelatin as a substitute for other protein in the test diet.
- 2 The cystinuric maintains a normal nitrogen and sulphur balance.
- 3 Gelatin feeding decreases the cystine output (as measured by the organic sulphur fraction of the urine) both absolutely and relatively.
- 4 The negative sulphur and nitrogen balance during gelatin feeding is diminished by adding tyrosine and tryptophane to the diet.
- 5 Evidence is supplied by these experiments to support the hypothesis that this anomaly concerns the intermediary metabolism and that in this case other amino acids are abnormally handled.

THE USE OF HISTIDINE HYDROCHLORIDE (LAROSTIDIN) IN THE TREATMENT OF PEPTIC ULCER^{*}

By JOHN T EADS, M D , *Philadelphia, Pennsylvania*

DURING the past three years a great deal of interest has been aroused by reports of the use of histidine hydrochloride (Larostidin) in the treatment of peptic ulcer. Due for the most part to favorable immediate results reported, this particular substance has enjoyed a widespread usage. In very few of the reports has there been a sufficient follow-period of observation for really accurate estimation of its true worth in comparison with the time honored dietary and alkaline régime. It has been the hope of the users of this treatment that the long drawn-out medical treatment of peptic ulcers could be avoided and that immediate and lasting improvement would follow. The earliest reports on immediate results were optimistic and tended to bear this out, but subsequent reports and two very recent ones have to a certain extent indicated the fallacy of this hope.

This treatment was introduced by Weiss¹ and Aron² of Strasbourg in 1933. Experimental ulcers were produced in dogs after the method of Mann and Williamson². These ulcers were considered caused by the lack of duodenal juice and its effect on the digestion of proteins. The investigators treated these ulcers by using various combinations of amino acids and produced favorable healing results in a small series of animals. Weiss and Aron⁴ then treated ulcer patients, at first with a combination of histidine and tryptophan, and reported evidence of healing. Later the use of histidine alone was found, by Aron,⁵ to produce the most favorable results.

Since this experimental work many other foreign authors have reported their results in the use of injections of histidine hydrochloride in the treatment of peptic ulcers in humans. Among these are Lenormand,⁶ Bogen-dorfer,⁷ Hessel,⁸ Bulmer,⁹ Stolz and Weiss,¹⁰ and Blum¹¹. Most of these authors report the immediate results in small series of cases and for the most part these results have been uniformly impressive. They have reported not only prompt symptomatic relief, but disappearance of roentgenographic signs and reduction in gastric acidity.

In only one or two instances has a follow-up period been of sufficient length to determine what happens to the excellent immediate results reported. Weiss,¹² in a late report, reports on the treatment of 91 ulcer patients over a period of 18 months.

In this country there have been fewer reports. Volinn and McLaughlin¹³ reported on a series of 21 patients in 1935. In 1936 Volinn

^{*} Received for publication June 9, 1936.

From the Medical Department, Jefferson Hospital, Philadelphia. The preparation of histidine solution used in this series of treatments is Larostidin supplied by Hoffmann-La Roche, Inc., Nutley, N. J.

and McLaughlin¹⁶ reported on 73 patients, a continuation of their previous preliminary report. They report in both publications 79 per cent of the cases clinically improved after six months with 21 per cent failures. They also report diminution in gastric acidity.

Eads¹⁴ made a preliminary report on the treatment of 35 cases of peptic ulcers with histidine with 65 per cent showing immediate clinical improvement and 35 per cent considered as failures. He found little or no effect on the acid curve. Six of his cases presented roentgenographic evidence of disappearance of the ulcer deformity.

Rafsky¹⁵ reported a series of 26 cases so treated with symptomatic relief obtained in 19 over a four-month period. He observed marked reduction of acid. Practically all of these reports were made on ulcer patients treated as ambulatory cases and with little or no dietary restrictions.

The latest reports on the use of histidine hydrochloride in the treatment of peptic ulcer are those by Sandweiss¹⁷ and Martin¹⁸. These authors treated a series of 40 patients and 41 patients, respectively. They had also a control series of patients treated with diet and alkalis for approximately the same length of time with follow-up periods of one year or more. They, too, found some very favorable immediate results from the use of histidine treatment but after an observation period of from a few months to a year or more found a high percentage of recurrence of symptoms—higher in those patients treated with histidine than in the series treated with diet and alkalis alone.

Sandweiss reports that 85 per cent of patients showing remissions of symptoms due to the histidine treatment returned with ulcer symptoms within six months after treatment. He does not advise the routine use of histidine in the treatment of peptic ulcers but believes it may have a place as an additional weapon in the regular medical treatment armamentarium.

Martin found that his percentage of recurrences was larger than in those cases treated by diet and alkaline therapy. He felt that the results of histidine therapy were symptomatic and transient.

Both Sandweiss and Martin report very little effect on the gastric acidity in their series of cases treated with histidine hydrochloride.

The present report deals with 85 cases of peptic ulcer which have been treated with daily intramuscular injections of a 4 per cent solution of histidine hydrochloride. The number of injections has varied from 15 to 36 with 70 cases receiving 24 injections each.

Each patient was diagnosed definitely a case of peptic ulcer, clinically and by positive roentgenographic findings.

There were 77 cases of duodenal ulcer and 8 cases of gastric ulcer. The average duration of symptoms was six years. The shortest history of symptoms was two months and the longest history indicated 12 years' duration. Fifty-five of these cases had been on previous ulcer treatment, usually consisting of some form of dietary restriction plus alkaline medication.

Eight of these patients had undergone previous surgical operations for their conditions—two having had a perforated ulcer with repair and six having had gastro-enterostomies

In the majority of cases several analyses of the gastric acidity were made before, during and at the completion of the course of treatment

All were examined roentgenologically before institution of the treatment, several during the course of the treatment and all at the completion of the course

Records were kept with regard to symptomatology, weight, et cetera, during the course of treatment

Sixty cases were treated as strictly ambulatory cases with little or no dietary restrictions. Twenty-five cases were treated as hospital cases, but not confined to bed. Ten of these were restricted somewhat as to diet and given occasional doses of alkalis

The patients have been separated into two groups—one group of 45 cases which has been followed for a period of approximately 18 months, the other group of 40 cases which has been followed for a period of six months

IMMEDIATE RESULTS OF HISTIDINE TREATMENT

There were no untoward reactions in any of the cases treated. Temperatures, blood pressures, pulse rates and blood counts were unaffected

There was very little alteration in the gastric acidity. Only eight patients showed any appreciable diminution in acidity and these were those having marked hyperacidity

Eight patients presented roentgen-ray evidence of immediate healing by disappearance of radiological signs of the ulcer. About half of the remainder showed some improvement in the roentgen-ray findings, such as lessened irritability, spasticity and tenderness in the region of the ulcer deformity. The remaining patients exhibited no change in the roentgenologic findings. Gastric ulcer patients presented the best response to the treatment from the roentgenologic point of view

Those patients presenting evidence of obstruction were not benefited by the injections and in two cases were made worse by the treatment

All of the cases previously operated upon showed immediate signs of improvement clinically. Five of these remained clinically improved after one year of observation

A gain in weight accompanied clinical improvement. In some instances this was quite rapid. However, while this gain in weight persisted during the active treatment, it tended to drop off and even be lost during the follow-up observation period in many instances. An increase in appetite and sense of well-being was also experienced in those cases showing immediate improvement

In most cases in which clinical improvement was noted it appeared early in the course of treatment, usually before five injections had been given

In only a few of the cases which showed improvement, was the suggested full number of 24 injections given before relief was obtained. In six cases, 36 injections were given without benefit. In a few cases after 24 injections had been given, there was some improvement noted a few weeks after completion of the course. This suggested some delayed benefit, but it was not permanent. Generally, those cases showing the greatest clinical improvement did so after only a few injections, those having 24 or more injections showed the poorest response.

Gastric ulcers presented the best response clinically as well as from the roentgenologic point of view. Those patients in the younger group with shorter histories and with no complicating factors such as obstruction or hemorrhage also responded more rapidly and more completely to the treatment.

The following tables show results in the two groups of patients, and the percentage of recurrences in those cases showing immediate improvement. These 85 cases have been observed over periods varying from six to 18 months. There are 10 other cases which have been treated but are not included in this series because they failed to return for check-ups and their records are incomplete.

TABLE I
45 Cases 39 Duodenal Ulcers, 6 Gastric Ulcers

Observation time	X-ray healed	X-ray improved	Clinically improved	Unimproved	Recurrence of Symptoms
1 month	6	13	28 (62.2%)	17 (37.7%)	—
6 months	6	11	18 (64.3%)	—	10 (35.7%)
12 months	5	9	14 (50%)	—	14 (50%)
18 months	5	4	9 (35.7%)	—	18 (64.3%)

From table 1 can be seen that of the 28 cases showing immediate evidence of healing 35.7 per cent presented recurrence of symptoms within six months. At the end of 18 months 64.3 per cent show a return of symptoms.

TABLE II
40 Cases 38 Duodenal Ulcers, 2 Gastric Ulcers

Observation time	X-ray healed	X-ray improved	Clinically improved	Unimproved	Recurrence of Symptoms
1 month	2	14	23 (57.5%)	17 (42.5%)	—
6 months	2	6	9 (39.2%)	—	14 (60.8%)

In table 2, 23 cases, or 57.5 per cent showed clinical evidence of healing. Of these, after a six months observation period 14 cases or 60.8 per cent presented a return of their symptoms. This group comprised older patients with longer histories than the group outlined in table 1. There were only

two gastric ulcers in this group both of which presented both roentgen-ray and clinical evidence of healing and remained well. Four of the cases in this group showed evidence of obstruction and did not benefit at all by the treatment.

DISCUSSION

It would seem therefore from the literature on the subject of histidine hydrochloride therapy in the treatment of peptic ulcers that whereas the immediate results secured may be generally favorable, this favorable effect is not continued in a large percentage of cases.

The mechanism by which histidine therapy produces benefit in those cases showing immediate improvement is by no means satisfactorily explained. The theory of Weiss and Aron postulated a deficiency in protein metabolism, with consequent loss of mucosal resistance. It is not accepted by many investigators. Some have held that the stimulation of an increased secretion of mucin might have a bearing, others that there is an analgesic effect produced by the injections. No doubt some of the favorable effects may be due to a psychic effect produced by the injections of a new substance with a considerable reputation. The true mechanism is not yet fully understood.

As other observers have found, the immediate results obtained in the use of histidine hydrochloride are excellent in a large number of cases of uncomplicated peptic ulcer. They compare very favorably with the best results obtained from the rigid dietary, alkaline regimen. However, their end-results after fairly short observation periods are not as good as the end-results following the orthodox medical treatment.

Yet, there seems to be a place for the use of histidine in the treatment of peptic ulcers, for in many cases relief of symptoms is so prompt and so spectacular that this immediate effect alone would justify its use. It would seem logical to employ this new agent as an adjunct to our regular medical treatment.

From the observation of its usage so far reported, histidine hydrochloride therapy cannot supplant the dietary-alkaline medical treatment, but it may be a valuable addition to this treatment, particularly in those cases which do not respond readily to the orthodox measures. In those cases in which further surgery is contraindicated histidine therapy offers aid, such as marginal ulcers and reactivated ulcers following surgical procedure. No attempt has been made to institute a second course of injections after six months in order to determine if there would be any benefit resulting from such a procedure. It might be well to do this.

CONCLUSIONS

Follow-up periods of from six months to 18 months have shown that the favorable results obtained immediately during the active course of treatment

with histidine hydrochloride are not continued in from 35 per cent to 65 per cent of the cases

From the present indications it would appear that the use of histidine alone offers end-results of less lasting benefit than the regular dietary and alkaline therapy in the average peptic ulcer patient. However, combined with the regular orthodox medical treatment, histidine may hasten the good results expected. It certainly is worth trying in those cases resistant to the usual treatment. Further study of the histidine injection treatment should be continued.

THE RELATIONSHIP OF BACILLARY DYSENTERY TO DISTAL ILEITIS, CHRONIC ULCERATIVE COLITIS AND NON-SPECIFIC INTES-TINAL GRANULOMA

By JOSEPH FELSEN, M D , *New York, N Y*

THE purpose of this communication is to present for critical consideration certain data which have been collected to support the contention that acute bacillary dysentery, acute and chronic distal ileitis, chronic ulcerative colitis and chronic non-specific intestinal granuloma have a common pathogenesis. The evidence to be offered will be considered under the following sub-divisions, viz epidemiological, clinical, serological, bacteriological, pathological and roentgenographical. An effort will then be made to correlate the findings reported under the respective headings and to apply them in diagnosis and therapy. The material which forms the basis for this study includes 400 cases of acute bacillary dysentery (1 major epidemic, 6 minor outbreaks, sporadic cases), 29 cases of acute distal ileitis, 22 cases of chronic distal ileitis, 18 cases of combined chronic ileocolitis and 84 cases of chronic ulcerative colitis. The period covered is from September 1933 to June 1936. These data are supplemented by a 9 to 12 months follow-up study of the Jersey City epidemic which has covered 122 out of an original group of 210 hospitalized patients.

EPIDEMIOLOGY

In the United States the seaport cities are the chief endemic areas for acute bacillary dysentery. The general geographic distribution of acute distal ileitis, chronic distal ileitis and chronic ulcerative colitis corresponds to that of bacillary dysentery. Inquiries show that there are no published or unpublished statistical data now available on these diseases from any source, including the United States Army, United States Public Health Service and the American Public Health Association. The reason is obvious, as ileitis, chronic ulcerative colitis and non-specific granuloma have been regarded as diseases of uncertain etiology. The increasing frequency of observation of these diseases during the last decade is believed to be associated with the increase in bacillary dysentery and not due merely to greater keenness in diagnosis. Outbreaks of dysentery in the New York area occur both in winter and summer often in hospitals through improper isolation of unrecognized cases.

Contact infection in chronic distal ileitis and chronic ulcerative colitis occurs chiefly during the stage of acute bacillary dysentery when the specific

* Received for publication June 19, 1936
From the Department of Laboratories and Research The Bronx Hospital, New York, N Y

organisms are present in the feces. The incidence of contact infection in this series of reported cases of chronic disease is 37.4 per cent, a rather high figure since the original source of infection is difficult to determine after one or more years have elapsed. Conjugal infection is relatively common if the couple were married prior to the onset of the original attack of bacillary dysentery or if one partner, involved prior to marriage, still harbors the

FIG. 1. Acute bacillary dysentery (Flexner Y), Stages 1 and 2. Arrow points to hyperplastic lymph nodules (Stage 1). Scattered over the remainder of the mucosa are multiple areas of focal lymphoid necrosis appearing like the mouths of tiny diverticula (Stage 2).

organism. Evidence of conjugal infection occurred in cases 5, 10, 35, 43 (table 1). This does not necessarily signify that both husband and wife will develop chronic ulcerative colitis, or ileitis, but that clinical and laboratory data will often reveal the presence of a previous dysentery infection with the same organism in both.

Because of the importance of epidemiological studies in establishing the pathogenesis of the chronic intestinal lesions a brief summary of some of the

cases will be given. In each instance there was a coincident time factor and the chronic disease represented a definite continuation of the acute phase in a previously healthy individual. Except where otherwise specified the laboratory studies were made in the chronic stage. Titers given refer to the agglutinating power of the patient's serum for dysentery bacilli. In contact cases the titers given are for the same strain of the organism.*

Note In this and the following tables empty spaces indicate no examination made "0" signifies negative, "+" signifies positive F (Flexner Y), MD (Mt Desert), PH (Park-Hiss), SD (Sonne-Duval), S (Schmitz) These strains are all of the mannite-fermenting Flexner type Owing to the heterogeneity of the Flexner antigen several strains were sometimes agglutinated by the same serum Only highest titers are given except where a special point of interest is involved

EPIDEMIOLOGICAL DATA IN CASES OF CHRONIC ULCERATIVE COLITIS (TABLE 1)

Case 2 Male, aged 45 Duration of disease 15 years Started during outbreak of dysentery in U S Army, AEF, during the World's War Titer 1 320

Cases 59 and 5 Mother, aged 57 and daughter, aged 32 Original infection contracted in China 19 years ago Mother's titer 1 120 Daughter's titer 1 160 Bacteriophage present in feces of both Daughter's husband of a recent marriage (three months) now has ulcerative colitis and shows a titer of 1 160 against the

same strain. Two of her children by a previous marriage have had repeated attacks of bloody diarrhea since birth, diagnosed as "colitis." These children are now being treated for colitis abroad.

Case 10 Female, aged 35. Duration three years. Titer 1:160 and bacteriophage present in feces. Husband had acute dysentery at time of onset of wife's symptoms and now has a titer of 1:100.

Case 11 Female, aged 41. Duration one year. Started during outbreak of acute bacillary dysentery in Mexico City. Three others in party definitely diagnosed by attending physician. Titer 1:160. Fecal culture positive.

Cases 15 and 16 Male, aged 40. Duration one-half year. Titer 1:320. Male, aged 35, brother, duration one-half year, titer 1:100. Child of latter has had diarrhea for approximately one-half year, titer 1:100. Two others in family affected but not examined.

FIG 2. Acute bacillary dysentery (Mt. Desert), Stage 3. Discrete and confluent ulceration.

Case 21 Male, age unknown. Duration one year. Follow-up of Jersey City dysentery epidemic.¹

Case 22 Male, aged 22. Duration one year. Titer 1:100. Sister admitted to hospital with appendicular form of acute bacillary dysentery, and at operation there was found acute distal ileitis with mesenteric and mesocolic lymphadenitis. Fecal culture positive and bacteriophage present. Titer 1:100.

Case 35 Male, aged 37. Duration one and one-half years. Titer 1:640. Wife affected during acute stage. Titer 1:160.

Case 38 Female, aged 47. Follow-up of Jersey City epidemic.

Case 39 Male, aged 38. Duration one year. Follow-up of Jersey City epidemic. A son, who was also affected during the epidemic, is free of symptoms.

FIG 3 Case 55, table 1 Chronic ulcerative colitis with polyposis cystica Arrow points to ileocecal valve Accession No 7160

FIG 4 Case 3, table 2 Obstructive granulomatous lesion in distal ileum
Accession No 7938

Case 40 Male, aged 22 Duration two years Titer 1 640 Fecal culture positive and bacteriophage present At onset of disease nursed friend ill with "dysentery" who afterwards died The necropsy findings were chronic distal ileitis and chronic ulcerative colitis with polyposis cystica

Case 43 Male, aged 50 Duration one year Titer 1 100 Bacteriophage present in feces Wife had dysentery at onset of patient's disease Titer 1 160

Case 44 Male, aged 29 Duration one year Follow-up of Jersey City epidemic

Case 49 Female, aged 31 Duration one year Titer 1 320 Dysentery started

FIG 5 Case 8, table 2 Sketch of ileocecal region Note polypoid areas of intact mucosa, serpiginous and linear ulcerations The process extends into the appendix Accession No 9273

during outbreak in Russia in which a party of visiting scientists, including the patient, were affected Fecal culture positive

Case 51 Female, aged 26 Duration one-half year Titer 1 320 Fecal culture positive Dysentery incurred during outbreak at institution for children where patient worked as practical nurse Her child died of acute bacillary dysentery and necropsy revealed a diffuse acute inflammation of the small and large intestines with follicular hyperplasia and necrosis and an associated mesenteric lymphadenitis

Case 56 Female, aged 35 Duration six years Titer 1 320 Mother, sister and brother have a similar condition but only the sister consented to examination Titer 1 40, subdiagnostic, bacteriophage present in feces

FIG. 6 Case 1, table 3 Sharply segmental and granulomatous type of distal ileitis
Accession No 7500

The possibility of familial contact infection is well illustrated by the following case

Case 67 Male, aged 26 Duration 12 years Titer 1 320 Bacteriophage present in feces Eight others in family affected Upon sigmoidoscopic examination two sisters showed typical lesions of chronic ulcerative colitis One sister had a titer of 1 320 with bacteriophage present in feces Three of her young children have had chronic diarrhea since birth, one having died of it during infancy The other sister had a titer of 1 320 One cousin died of "intestinal hemorrhages" A grandmother and uncle have had "chronic colitis with diarrhea" for many years No further examinations were permitted

Case 68 Male, aged 22 Duration five years Titer 1 160 Two sisters affected with "chronic diarrhea," one having a titer of 1 320, the other 1 160

Case 70 Female, aged 25 Duration one year Follow-up of Jersey City epidemic

Case 74 Female, aged 40 Duration one year Follow-up of Jersey City epidemic

Case 84 Male, age unknown Duration one year Follow-up of Jersey City epidemic

Case 85 Male, age unknown Duration one year Follow-up of Jersey City epidemic

EPIDEMIOLOGICAL DATA IN CASES OF CHRONIC DISTAL ILEITIS (TABLE 3)

Case 14 Female, aged 20 Duration one year Follow-up of Jersey City epidemic

Case 15 Female, aged 21 Duration one year Follow-up of Jersey City epidemic

Case 17 Male, aged 32 Duration two years Titer 1 160 Started during an outbreak of bacillary dysentery following banquet at hotel

Case 22 Male, aged 16 Duration six years Titer 1 320 Sister who nursed him had resection of ileocecal granuloma one year ago Titer 1 320 Her husband has had chronic diarrhea and intestinal symptoms for several years Titer 1 160

There is a possibility that domestic animals may be the source of infection with *B. dysenteriae* in some cases. The only evidence pointing in this direction is that in three instances in this series diarrhea in a dog or cat definitely preceded the disease in the human by six to 24 hours, a common incubation period for acute bacillary dysentery.

CLINICAL

Twenty-nine instances of acute inflammation of the distal ileum were noted as an early manifestation of bacillary dysentery. These cases have been conveniently classified under the appendicular type of bacillary dysentery because of the close clinical resemblance to acute suppurative appendi-

citis^{2,3} There is a short prodromal period of nausea, headache and moderate pyrexia followed by pain and tenderness in the right lower quadrant of the abdomen. The tenderness tends to shift with change in position of the body. There is generally little or no rigidity. The spastic ileum or sigmoid may be felt. At operation, the ileum is found to be reddened, edematous and thickened, the area involved being rather sharply demarcated from contiguous healthy bowel. The vascular arborizations show intense congestion and there is a diffuse acute mesenteric and mesocolic lymphadenitis. There may be signs of an acute upper respiratory infection, particularly in the Sonne-Duval type of dysentery in children. We have not seen acute distal ileitis with mesenteric lymphadenitis in any disease other than bacillary dysentery.

The development of chronic distal ileitis from the acute form of the disease in the same individual has been seen in 14 instances (Table 2, cases 1, 2, 5, 9, 10, 11, 12, 13, table 3, cases 10, 11, 12, 13, 14, 15). The development of chronic ulcerative colitis following an attack of acute bacillary dysentery in the same individual has been seen in 25 instances (Table 1, cases 11, 18, 21, 22, 29, 33, 38, 39, 40, 41, 43, 44, 45, 46, 51, 56, 58, 61, 62, 70, 72, 77, 81, 84, 85). There is not always a clear line of demarcation between the ileitis and colitis group since bacillary dysentery affects both the small and large bowel simultaneously. Usually, the ileum or colon alone is affected in the chronic form of the disease, but the ileocecal valve does not necessarily limit the extent of the lesion. Although the transition stages from acute bacillary dysentery to chronic ileitis or ulcerative colitis were first noted in sporadic cases, perhaps the best illustration is offered in the follow-up studies of the Jersey City epidemic⁴. Of an original group of 210 hospitalized patients 122 were re-studied nine to 12 months later. Forty-six of these patients (37.7 per cent) had persistent or recurring intestinal symptoms or signs, viz. eight (6.5 per cent) had diarrhea with blood, mucus and pus, 12 (9.8 per cent) had a watery diarrhea without gross blood, three (2.4 per cent) had bloody evacuations without diarrhea and 23 (19 per cent) had miscellaneous intestinal disturbances such as recurring attacks of abdominal cramps. In the above group of 46 patients roentgenographic evidence of chronic ulcerative colitis was obtained in eight, sigmoidoscopic proof in two, specimens showing chronic distal ileitis were obtained at operation in two cases and necropsy in one. Thus visible evidence of chronic distal ileitis or ulcerative colitis was obtained in 13 (10.7 per cent) of a total of 122 patients nine to 12 months after the initial attack of bacillary dysentery or roughly one out of every 10 patients. It is possible that these figures would have been higher if routine roentgenographic examinations had been made in every return study.

Abortive and atypical types of acute bacillary dysentery have been recently encountered^{1,5}. They are frequently unrecognized clinically or incompletely studied in the laboratory. In the asymptomatic form, epidemic type, the fecal cultures are positive and intestinal lesions are seen through

TABLE IV

Follow-up Studies of Jersey City Epidemic of Bacillary Dysentery

Total number of hospitalized cases	210
Total number of follow-up cases	122
(a) Roentgenographic evidence of chronic ulcerative colitis	8 (6.5 per cent)
(b) Additional cases with sigmoidoscopic evidence of chronic ulcerative colitis	2 (1.7 per cent)
(c) Chronic distal ileitis (two at operation, one at necropsy *)	3 (2.5 per cent)
* Almost entire ileum and all of colon involved	
Proof of chronic ulcerative colitis or ileitis nine to 12 months after the onset of acute bacillary dysentery (Flexner)—10.7 per cent (13 out of 122, or approximately 1/10)	

the sigmoidoscope, but the patients have no complaint. The organisms disappear in a week to 10 days and the lesions heal shortly thereafter. These patients are discovered only in the course of epidemiological surveys. In the afebrile type the clinical course is typical except for a normal or almost normal temperature. In the constipated type, a bowel movement may not occur for three or four days. This occurs in individuals who usually have one or two normal bowel movements a day. Sometimes a single watery stool is noted at the onset of the disease. Constipation is a frequent symptom in acute bacillary dysentery immediately following the acute stage (seven to 10 days) and suggests Nature's effort at splinting the bowel to favor healing. The meningitic form suggests an acute meningococcus meningitis, but lumbar puncture reveals a clear fluid, normal cytology, the presence of sugar, no globulin and negative culture. Every patient seen thus far has had an associated labial or nasal herpes. Diarrhea usually ensues shortly after the onset of meningitic symptoms. The appendicular form has already been described under acute distal ileitis. Three cases of the agranulocytoid type have been seen, the blood picture bearing a very close resemblance to that seen in agranulocytosis. This phenomenon will be referred to again in connection with the myelotropic toxin.

In chronic ulcerative colitis and ileitis "mendicant's posture" has been frequently encountered. This term is applied to a peculiar position of the body and a characteristic gait seen in ambulatory patients during the period of acute exacerbation of intestinal symptoms. It disappears completely during the remission stage. The patient is generally quite emaciated and dehydrated from frequent watery evacuations. His pallor, hollowed cheeks and sunken temples form an almost funereal background to an expressionless face, or to a worried look which betokens great physical discomfort. In walking there is exhibited a peculiar shuffling gait, the cervical and dorsal spine being bent forward and held quite rigid. The shoulders are high, the head is bowed and the abdomen somewhat concave. The patient appears to be looking at the ground and only casually glances upward at passersby without moving his head. One hand is held on the mid-section or is placed upon the hip. It seems as though only a distaff would be required to complete a picture of the proverbial beggar. It is apparently a natural position

for these patients who suffer from almost constant cramps or abdominal soreness

SEROLOGY

Diagnostic, agglutination titers against *B dysenteriae* were obtained in 22 cases of chronic distal ileitis, 18 cases of combined ileocolitis and 76 cases of chronic ulcerative colitis, or in 116 (93.5 per cent) out of a total of 124 cases. Of the eight cases in which the titers were not done or found to be at the subdiagnostic level, one (case 29, table 1) had a positive fecal culture, three (cases 38, 39, 61, table 1) were originally seen in the Jersey City epidemic and the remaining four (cases 20, 25, 50, 71, table 1) were negative for all bacteriological or serological evidence of bacillary dysentery. All of the chronic cases included in this study were clear cut examples of the disease diagnosed by the usually accepted criteria noted under "Diagnosis." Supplementary data were furnished by pathological study of operative or necropsy specimens. In the serological examinations 18-hour viable broth cultures, the gross test tube method, four hours incubation at 55° C and refrigeration overnight were used. Control agglutination studies of 300 patients from the same area showed diagnostic titers in only 4.6 per cent for all types except *B dysenteriae* Sonne-Duval.⁶ In the latter no positives were obtained. Titers of 1:100 or over were regarded as diagnostic in all except the Sonne-Duval type in which 1:50 or over was considered positive.* Most of our acute mild Flexner and Sonne-Duval infections gave only transitory titers. Hiss⁷ calls attention to the frequent occurrence of weak agglutination titers in bacillary dysentery. It suggests the possibility that a negative titer in chronic ulcerative colitis or ileitis may be inconclusive. In further support of this contention additional evidence is furnished by follow-up titers nine to 12 months after the Jersey City epidemic in 106 cases. Thirty-two (30 per cent) showed a diagnostic titer and 74 (70 per cent) a subdiagnostic or negative titer. Of 11 patients who developed chronic ulcerative colitis or ileitis, eight (73 per cent) showed a follow-up diagnostic titer (table 1, cases 21, 44, 70, 74, 84, table 2, case 13, table 3, cases 14 and 15), one (9 per cent) showed a negative titer (table 1, case 38), the remaining two (18 per cent) not having been tested (table 1, cases 39 and 61).

In some cases peculiar cross agglutination titers were obtained in the chronic stage. Cases 21 and 70, table 1, in which original titers of 1:120 against the Flexner organism were found during the epidemic, showed only 1:40 against the same organism at the end of one year, but a titer of 1:100 against the Mt. Desert and Park-Hiss strains. These results are probably

* There is a lack of unanimity of opinion with regard to diagnostic titers in bacillary dysentery. A rising agglutination titer in acute bacillary dysentery is diagnostic, but in some cases it may not go beyond 1:100. The low titers (1:50) obtained in Shiga-Kruse or Sonne-Duval infections have been repeatedly shown by other investigators. As in the chronic forms of the disease agglutination titer is to be regarded as only one link in the chain of evidence. It should be used only in conjunction with epidemiological, clinical, pathological, bacteriological and roentgenographical studies.

due to the antigenic heterogeneity of the Flexner group. The Flexner organism is said to contain at least four antigenic components, V-W-X and Z,⁸ which are present in every strain but with one component predominating over all the others. Ordinarily this is sufficient to stamp a given organism as a definite type serologically. In *B. dysenteriae* Flexner Y, however, the antigenic components are more evenly balanced and the serum prepared against it has a more irregular and wider range of agglutination against other members of the Flexner group. Owing to the many variants of the Flexner organism a sufficient number of smooth, agglutinable strains should be used, particularly those prevalent in the area in which the studies are being conducted. The Jersey City, Mt. Desert and Park-Hiss strains are always included in our routine set-up. In actual practice, it appears that it is chiefly the severe cases of acute bacillary dysentery or patients with residual infections who develop the chronic lesions. Follow-up agglutination studies of patients who had acute distal ileitis which healed completely, as shown by clinical and roentgenographic examinations, revealed a marked drop in titer at the end of six to 12 months, sometimes to a sub-diagnostic level.

BACTERIOLOGY

It is generally accepted that positive fecal cultures in acute bacillary dysentery are usually not obtained after the first or second week. Repeated and persistent cultural examinations of the feces or intestinal mucosa in chronic ulcerative colitis and ileitis were positive for *B. dysenteriae* in 10 cases out of 70 cultured (14.2 per cent) viz. table 1, cases 11, 18, 29, 40, 48, 49, 51, 76, table 2, cases 3 and 13. In one instance of chronic distal ileitis the organism was recovered approximately one year after resection of the distal portion of the ileum.

Bacteriophage was found in 20 (39.2 per cent) out of 51 cases examined, viz. table 1, cases 5, 8, 9, 10, 13, 16, 30, 40, 43, 54, 55, 59, 65, 67, 71, 72, 78, 83, table 2, case 17, table 3, case 4. It appeared to be group rather than type specific and, when taken in conjunction with other findings, of definite value in diagnosis. In the examination of 100 normal controls, bacteriophage was present in one fecal specimen.

The more often fecal and sigmoidoscopic cultures are repeated, the higher will be the percentage of positive findings. Fresh mucosal scrapings with a dull curette or crypt aspirations are better for culture than feces. For aspiration a heavy walled capillary tube is used (5 mm outside diameter, 35 cm long). A fusiform dilatation, sufficient to hold three or four drops of fluid, is blown into the tube about 2 cm from the distal end which is bent slightly for better approximation to the bowel wall. This inexpensive device, prepared in the laboratory, is inserted through a 12 inch sigmoidoscope, the mucosal aspiration is made by sight and the material seeded directly on a fresh Endo plate. A small one and one-half inch rubber bulb without a valve, but with a hole at the bulbous end is used for

aspiration The bulb is squeezed and the index finger then placed over the hole before suction is started This affords excellent control with a minimal amount of positive pressure in the capillary tube The dilated portion holds sufficient fluid for culture, warm stage and wet smear on hematoxylin examinations for *Endameba histolytica*

Positive culture of *B. dysenteriae* in chronic ulcerative colitis and ileitis is neither an incidental and irrelevant finding, nor is it indicative of a healthy carrier Our experience has been that these patients have never fully recovered from the original attack of bacillary dysentery and that careful physical, roentgenographic and sigmoidoscopic examinations always reveal intestinal lesions Control studies in more than 300 cases failed to reveal *B. dysenteriae* in the feces of individuals free of all manifestations of the disease Our experience in bacillary dysentery points to the existence of "sick carriers" rather than "healthy carriers" In cases 11, 29, 40 and 49, table 1, there were no intestinal or other physical complaints in remission periods nor was an organic lesion suspected by the referring physicians Yet *B. dysenteriae* was recovered in each instance, sigmoidoscopic evidence of ulceration was present and was corroborated in three cases by roentgenographic examinations In two hospital outbreaks in New York City (Sonne-Duval and Flexner Y) the children were at first regarded as carriers or the cultures considered as merely incidental findings Bloody diarrhea in a child who appeared quite well and who had no particular complaints or pyrexia did not correspond to the orthodox picture of acute bacillary dysentery Necropsy findings and epidemiologic surveys revealed the true nature of the disease It recalls to mind the sudden deaths occasionally seen in Sonne-Duval dysentery

Experimental and clinical studies suggest that the primary intestinal lesions in acute bacillary dysentery are due to a thermostabile endotoxin which is excreted from the blood vessels through the wall of the bowel into the lumen Flexner⁹ called attention to this important mechanism in 1906, stressing toxin excretion rather than the local action of the organism itself as being the cause of the intestinal ulcers Zimsser¹⁰ described typical diarrheal and nervous symptoms following the intravenous injection of large doses of toxin into rabbits We have repeatedly failed to infect rabbits by the oral route, but have readily produced diarrhea and intestinal lesions by the intravenous injection of the living organisms or toxin These organisms have been recovered under proper control conditions from the feces of rabbits 24 to 48 hours after the intravenous injection of 18-hour broth cultures

Re-absorption of toxin from the intestine occurs, producing a vicious cycle in the severe toxic cases The major pathologic changes in acute bacillary dysentery are usually produced within the first 24 to 48 hours There are probably a number of toxins produced by *B. dysenteriae* Besides the enteric toxin and thermostabile neurotropic exotoxin, described by Olitsky and Kligei,¹¹ there also appear to be arthritic and myelotropic toxins

which have an affinity for the joints and bone marrow respectively. The incidence of arthritis in both acute bacillary dysentery and chronic ulcerative colitis is quite high. Our figure for the latter is 15.4 per cent (table 1, cases 2, 3, 6, 8, 10, 12, 13, 14, 17, 24, 26, 27, 30, 49, 54, 66, 67, 82, table 2, case 6. Nineteen cases of a total of 124). The larger joints were more commonly affected, particularly the wrists, knees or ankles. Individual fingers or toes were involved less frequently. The exacerbation and remission of joint symptoms corresponded to the alternating periods of recrudescence and subsidence so characteristic of chronic ulcerative colitis and ileitis. Roentgenograms taken during the acute stage of arthritic symptoms revealed peri-articular inflammation in two cases (table 1, cases 10 and 26). The intradermal injection of 0.1 cc dysentery toxin (approximately 1 MLD white mouse) produced a sudden and marked flare-up of joint pains in many instances. This was particularly noteworthy in case 30, table 1, the patient requiring morphine for relief.

The only evidence suggesting a myelotropic toxin is the frequency of leukopenia and the occurrence of three instances of marked fulminating neutropenia resembling agranulocytosis in acute bacillary dysentery.¹² The toxin appears to affect the endothelium of the bone marrow sinusoids preventing the migration of granulocytes from their extra-vascular zone of formation into the circulating blood. Pathologic study reveals no deficiency in leukopoiesis or erythropoiesis in the marrow.

The secondary intestinal lesions are essentially intramural infections with the enterococcus, and hemolytic and non-hemolytic *B. coli*. These organisms gain entrance through the denuded intestinal mucosa, advance along the lymphatic pathways and are persistent and difficult to eradicate. Sudden, spontaneous remissions in chronic ulcerative colitis seem to be due to an increase in the immunity defense mechanism. Preliminary studies point to an increase in the agglutination and bactericidal titers of the blood during the remission stage. Recurrence of symptoms follows a lowering of this defense mechanism so that chronic ulcerative colitis or ileitis is often a cyclic disease corresponding to alternating periods of relatively high and low degrees of immunity. A knowledge of this natural trend should govern the evaluation of any given form of therapy.

The enterococcus and *B. coli* have been isolated from intramural abscesses and secondary lesions of the renal pelvis. Aspirated fluid from inflamed joints in acute bacillary dysentery, chronic ulcerative colitis and ileitis has proved persistently negative upon culture. Secondary toxin absorption effects may be present due to the presence of toxic anaerobes such as *B. welchii* in the bowel. This factor should be borne in mind in connection with intestinal oxygenation.¹³

PATHOLOGY¹⁴

In order to understand the pathological lesions in chronic ulcerative colitis and ileitis, it must be remembered that any part of the small or large

intestine may be involved during the stage of primary infection with *B dysenteriae*. "Skip" areas of segmental involvement may occur. The small and large intestine may be affected independently or concomitantly. In the former, the distal portion of the ileum is usually involved and in the latter, all or part of the large intestine including the appendix. In every case thus far studied sigmoidoscopic examination revealed acute lesions so that it may be stated that in the acute stage of bacillary dysentery the recto-sigmoid is always involved. Repeated sigmoidoscopic examinations starting within a few hours after the onset of symptoms indicate the earliest lesion to be a hyperplasia of the solitary acuminate lymph nodules which are affected in a multiple and punctate fashion. There is an acute diffuse inflammation of the overlying mucosa which is covered with a mucoid, blood-tinged or purulent exudate. Bleeding occurs after the slightest trauma such as passage of the sigmoidoscope or use of a dull culture cuvette. Follicular necrosis quickly ensues, but "weeping" of blood appears to take place even before superficial ulceration is evident. Studies at this stage were supplemented by necropsies on infants. The solitary acuminate lymph nodules are in various stages of hyperplasia and necrosis, the overlying mucosa being ulcerated and the necrotic lymph nodules appearing like the mouths of tiny diverticula. In the severe cases the entire lymph nodule is eventually destroyed. Adjacent areas of necrosis and ulceration coalesce, thus adding width and depth to existing ulcers. The necrotic mucosa is bordered by a marginal zone of polymorphonuclear leukocytes, some lymphocytes and plasma cells. Necrosis of the submucosal blood vessels underlying the ulcerated area occurs and is probably due to the dysentery toxin. The vessel wall ruptures and releases its contents into and through the ulcer. An intense vascular congestion is present throughout this period. In fatal cases serpiginous and geographic areas of denudation occur, the acute inflammation permeates the entire intestinal wall and death occurs from intense toxemia or perforation or both. This process generally takes about two to four weeks in adults in the Flexner and Sonne-Duval types of dysentery seen in the New York area. In infants, death is usually due to toxemia and dehydration which are apt to prove fatal within a few days to one week.

If one can judge from the follow-up figures of the Jersey City epidemic approximately 90 per cent of the cases of acute bacillary dysentery recover completely. The other 10 per cent recover partially or temporarily only to suffer periodic exacerbations and remissions every few weeks or months. In these cases the acute lesions do not heal. Ulcerations persist and spread and secondary intramural infection occurs. That this process is merely a perpetuation of the acute dysentery is borne out by repeated follow-up examinations which prove that neither have the intestinal ulcers healed nor have the symptoms ever cleared up. The disease has reached the chronic phase and whether the process is confined to the ileum or to the colon, the pathologic process is essentially the same. Mural fibrosis ensues and represents an attempt at healing. The lymph nodules are destroyed. Here and

there islands of mucosa may remain intact and often, due to the blockage of ducts by scar tissue and the accumulated secretion, may take on a polypoid appearance. In the ileum or cecum particularly, a granulomatous lesion may be encountered.¹⁵ It merely represents a productive type of inflammation. The presence of giant cells may suggest tuberculosis, but specific stains and guinea pig inoculations with the macerated tissue always prove negative. In general, the end result is an ulcerated, narrowed, thickened, infected, vascularized tube of connective tissue. This is the late stage of bacillary dysentery, perhaps more generally termed chronic distal ileitis, non-specific granuloma, and chronic ulcerative colitis. The pathological changes above described account for the roentgenographic findings in these diseases, viz Kantor's string sign of chronic distal ileitis,¹⁶ obstructive lesions at or near the ileocecal region (granuloma), irregularities of mucosal pattern (ulceration), loss of haustration, narrowing of the large bowel or polyposis. Fistulous tracts and secondary extramural abscesses occur as complications due to extension of the infection through the wall of the bowel. Fortunately the process is often a comparatively slow one so that when perforation does take place there is a well walled off area of inflammation which prevents a diffuse peritonitis.¹⁷ Residual infections with *B. dysenteriae* may occasionally be found in the mesenteric or mesocolic lymph nodes.

Pathological Reports Following is a brief summary of the relevant surgical pathology or necropsy findings in individual cases.

Chronic Ulcerative Colitis (table 1)

- Case 8 Ulceration, intramural infection with fibrosis of the cecum and ascending colon (Surgical resection)
- Case 45 Ulceration, intramural infection with fibrosis and polyposis cystica of the ascending, transverse and descending colon. Perforation of sigmoid (Necropsy)
- Case 55 Ulceration, intramural infection with focal abscesses, polyposis cystica of entire large bowel. Beginning perforation in sigmoid (Necropsy)

Combined Ileitis and Colitis (table 2)

- Case 3 Obstructing granuloma 10 cm of distal ileum (Surgical resection)
"Skip" type of lesion in colon (Postoperative study)
- Case 5 Ulcerative, non-stenosing type of ileitis involving 10 cm distal ileum
Chronic ulcerative colitis (Laparotomy without resection)
- Case 7 Ulcerative and productive type of distal ileitis involving 12 cm of ileum (partial resection) Chronic ulcerative colitis of the cecum and ascending colon (postoperative study)
- Case 8 Ulceration, mural fibrosis and polyposis of the distal 30 cm of ileum, appendix and entire colon (Necropsy)
- Case 11 Approximately the distal half of ileum and entire colon were the seat of innumerable discrete and confluent ulcers with many areas of low grade local peritonitis. Perforation of sigmoid (Necropsy)
- Case 13 Ulceration, mural fibrosis and polyposis of entire colon, perforation of sigmoid. Early granulomatous lesion distal 10 cm of ileum (Necropsy)
- Case 14 Segmental involvement of ileum approximately 60 cm from ileocecal valve, intramural infection with several sinuses connecting adherent ileum

- and cecum Chronic ulcerative disease with mural fibrosis of ascending colon (Surgical resection)
- Case 15 Chronic ulcerative lesion of distal ileum, with polyposis cystica in proximal colon to splenic flexure "Skip" lesion in upper sigmoid (Surgical resection)
- Case 16 Segmental ulcerative and productive type of ileitis 20 cm above ileocecal valve Similar lesions in appendix, cecum and proximal portion of ascending colon (Surgical resection)
- Case 17 Serpiginous and geographic ulceration with intramural infection from ileocecal valve to anus Many ulcers in healing stage located in distal 40 cm of ileum (Necropsy)
- Case 18 Ulcerative ileocolitis involving almost entire ileum, the appendix and colon Polyposis cystica coli with perforation in transverse colon

Chronic Distal Ileitis (table 3)

- Case 1 Segmental granulomatous type of inflammation involving ileum for a distance of 10 cm at a point approximately 15 cm above ileocecal valve (Surgical resection)
- Case 2 Stenosing, cicatrizing lesion of distal 10 cm of ileum (Surgical resection)
- Case 5 Ulceration with extensive mural fibrosis and stenosis distal 30 cm of ileum (Necropsy)
- Case 6 Ulceration with extensive mural fibrosis and stenosis of distal 35 cm of ileum (Surgical resection)
- Case 7 Thickening and linear ulceration of distal 5 cm of ileum (Surgical resection)
- Case 8 Involvement of several loops of ileum which were adherent to one another, with several sinus tracts between coils of intestine and mesentery Abscess in pelvis (Surgical resection)
- Case 9 Chronic non-obstructive distal ileitis (10 cm) with diffuse mesenteric lymphadenitis (Laparotomy without resection)
- Case 10 Distal 15 cm of ileum involved Extensive intramural infection, fibrosis with stenosis (Surgical resection)
- Case 12 Distal 12 to 15 cm of ileum thickened, inflamed Mesenteric lymphadenitis (Laparotomy without resection)
- Case 13 Distal 10 cm thickened and inflamed No evident stenosis (Laparotomy without resection)
- Case 14 Distal 40 cm of ileum thickened, stenosed and inflamed (Surgical resection)
- Case 15 Distal 20 cm of ileum involved Intramural infection and fibrosis Mesenteric lymphadenitis (Surgical resection)
- Case 16 Distal 30 cm of ileum involved Coils adherent with formation of two fistulous tracts Ileocolic fistula and abscess (Surgical resection)
- Case 17 Involvement of 37 cm of ileum at a point 50 cm above the ileocecal valve Inflamed loops adherent, thickened and covered with plastic exudate Mesentery thickened and adherent Productive, granulomatous type of inflammation with obstruction Adjacent portions of intestine exhibited old ulcers (Surgical resection)
- Case 18 Cicatrizing obstructive lesion distal 15 cm of ileum (Surgical resection)
- Case 19 Granuloma distal 7 cm of ileum causing almost complete obstruction (Surgical resection)
- Case 20 Thickening and inflammation distal 15 cm of ileum Mesenteric lymphadenitis (Resection not done)

Case 22 Granulomatous, obstructive lesion distal 10 cm of ileum (Surgical resection)

ROENTGENOLOGY

Roentgenographic evidence of chronic ulcerative colitis or ileitis was obtained in 84 cases examined. In 60 cases, only the colon was involved, all or in part, in 14 both the distal ileum and colon were involved and in 14 only the ileum was affected. The roentgenographic findings did not always correspond to the surgical pathology or necropsy findings. In the latter, particularly, the lesions found were more extensive than those visualized in the roentgenogram. In some cases the development of the chronic lesions could be traced roentgenographically.

Case 34, Table 1 Onset of the disease in 1932. At this time roentgenographic study of the intestinal tract proved negative. In April 1935, the films revealed chronic ulcerative colitis with polyposis cystica.

Case 66, Table 1 At onset of the disease in 1931 roentgenographic examination was negative. In June 1935, the pictures revealed chronic ulcerative colitis involving the entire large intestine.

Case 79, Table 1 At onset of the disease in 1935 no lesion was noted, but in April 1936, the cecum and ascending colon were involved.

Case 2, Table 2 At onset of the disease in December 1934, there was no evidence of ulcerative colitis. In May 1936, the ileum and entire colon were involved. This patient was observed clinically during both the acute and chronic stages.

DIAGNOSIS

The diagnosis of a typical case of acute bacillary dysentery is usually quite simple. A history of contact infection, a prodromal period of 12 to 48 hours of malaise, headache, anorexia and nausea, accompanied by a moderate elevation of temperature is followed by a profuse, watery diarrhea. The fever increases, cramps and tenesmus are marked and mucus, pus or bright red blood appears in the feces. Sigmoidoscopy reveals an intense acute inflammation with ulceration of the mucosa. The tender, spastic ileum and sigmoid can be felt through a thin abdominal wall. A leukopenia is often present at the onset of the disease and may continue throughout. Different strains of the same organism (e.g. Flexner) behave differently in this regard suggesting the presence or absence of a specific myelotropic toxin. Positive fecal cultures are usually obtained during the first week after which the bacteriophage and agglutination titer increase. The atypical forms of acute bacillary dysentery recently encountered include the afebrile, asymptomatic, constipated, appendicular, meningitic, agranulocytoid and Sonne-Duval. Outbreaks of Sonne-Duval dysentery have been recognized in the United States only in recent years. The child with bloody, diarrheal stools who may not appear to be ill should be isolated at once and studied intensively for *B. dysenteriae*. Contact cases of this type on hospital wards are relatively frequent and the outbreak may die out before delayed studies are completed.

The diagnosis of chronic dysentery is more difficult, particularly if the patient is seen for the first time one or more years after the initial infection. The diagnostic criteria in chronic distal ileitis, non-specific granuloma and chronic ulcerative colitis may be summarized as follows:

- (a) Epidemiologic History of contact infection at the time symptoms *first* appeared
- (b) Clinical Persistent or recurring attacks of abdominal cramps and diarrhea, sigmoidoscopic evidence of ulceration, pseudo-polypoid or mural fibrosis with stenosis, palpation of tender, thickened or spastic ileum or sigmoid, mendicant's posture on standing or walking¹⁸, chronic arthritis, the exacerbations being associated with periodic attacks of diarrhea
- (c) Roentgenographic Defects in the mucosal pattern, loss of haustration, narrowing of the bowel lumen, presence of the string sign, intrinsic obstructive lesion (granuloma)
- (d) Laboratory Culture of *B. dysenteriae* from crypt aspirations or mucosal scrapings, diagnostic bacteriophage in the feces, diagnostic agglutination titer of the blood. The skin test and intestinal smears for cytology may be used as supplementary aids in diagnosis.

Differentiation from amebic dysentery¹⁹ may be made as follows. In acute amebic dysentery the ulcers are discrete, undermined and often surrounded by a hemorrhagic halo. The intervening mucosa is not as acutely inflamed as in bacillary dysentery, but the late lesions of both diseases may be indistinguishable from one another through the sigmoidoscope. In amebic dysentery the ileum is not involved, the trophozoites can be detected in the diarrheal discharge and together with the cysts may often be recovered in the mucosal scraping or biopsy. The therapeutic test with emetine or a suitable substitute is a good one. The same may be said of the oxygen test, for after intestinal oxygenation the amebae appear in great numbers due to their avidity for oxygen. In amebic liver necrosis oxygen has a similar effect, the protozoa emerging quite rapidly from the wall and appearing in the drainage tube. Wet smear fixation in Schaudinn's fluid followed by the iron-haematoxylin stain should supplement all warm stage examinations. Double infections with *B. dysenteriae* and *B. typhosus* or *B. dysenteriae* and *Endameba histolytica* do occur since they generally have a common source. We have had two cases of each. This possibility should be borne in mind when patients are unusually refractory to treatment.

THERAPY

The ideal therapy of chronic distal ileitis, chronic non-specific granuloma and chronic ulcerative colitis is the prevention of bacillary dysentery. The typical and atypical forms must be recognized by the family physician and the patients promptly isolated. Every case of diarrhea, particularly in hos-

pitals and other institutions, should be isolated at once without waiting for the laboratory reports. No harm is done if the bacteriologic findings prove negative and this simple precaution may save the lives of many infants. Basically, it is a public health problem to be solved ultimately with the aid of adequate funds for disease prevention.

There must be stricter supervision of food-handlers, water supply and sewage disposal on land and on board ships. There must be complete freedom from political and business control, both of which foolishly perpetuate the very disease regarding which publicity is shunned. Prophylactic vaccination against *B. dysenteriae* during small outbreaks or epidemics is advisable, as indicated by experimental work on animals. Strains of relatively low toxicity may be used.

In acute bacillary dysentery, a potent dysentery antitoxin must be given within the first 24 to 48 hours to be most effective as the major damage is usually done during that period. It may be supplemented by the liberal use of castor oil in humble imitation of Nature's effort to rid the body of specific toxins and bacteria. Normal saline or 5 per cent glucose in saline should be used freely where indicated by hypodermoclysis or intravenously. Every patient with acute bacillary dysentery should be followed up for one year in order to safeguard him against the chronic lesions. Any patient with acute bacillary dysentery which lasts more than three weeks is a potential case of chronic ulcerative colitis or ileitis and should be treated as such.

In the chronic forms of dysentery active immunization may be effected by the use of D-C vaccine and D-C antiviral (the D-C referring to polyvalent strains of *B. dysenteriae*, *Enterococcus*, hemolytic and non-hemolytic *B. coli*)²⁰. Except during temporary acute exacerbations a high caloric, high vitamin diet should be used. Limitations based upon minimal residues are of doubtful value. It must be remembered that most of the small bowel is still functioning well. Intestinal oxygenation is used to control the anaerobes whose toxins are absorbed through denuded areas, to promote drainage of aerobes from the interstices of the intestinal structures and to quiet excessive intestinal peristalsis. Oxygen also serves as an efficient deodorizer of the foul discharges so commonly encountered. Surgical resection, except as an emergency procedure, is contraindicated as the operator generally cuts through infected bowel wall or overlooks "skip" areas with the result that recurrences are common. Repeated transfusions are valuable, particularly if recovered cases of chronic dysentery are used as donors. Professional donors are now being tested in order to determine specific blood agglutinins against *B. dysenteriae*. Those showing diagnostic titers are used for patients ill with acute or chronic bacillary dysentery, subject to the usual preliminary tests for grouping, cross matching and syphilis. Such transfusions have the advantages of blood from a homologous species in lessening serum reactions and supply both fluid and cells to combat dehydration and hemorrhage. They may be repeated as often as necessary and

preferably given by the direct method. The routine use of emetine to guard against a co-existing amebic dysentery is advisable.

SUMMARY

A correlated study of 553 cases of acute bacillary dysentery, acute and chronic distal ileitis and chronic ulcerative colitis points to their common pathogenesis. The development of the different stages has been seen in individual cases including those seen in a major epidemic. Attention is called to the absence of diagnostic agglutination titers in many recovered cases of acute bacillary dysentery and in some cases of chronic dysentery. Control studies and search for other primary etiologic factors proved negative. Secondary factors influencing the course of the disease or present as the result of it were considered as not falling within the scope of this paper. The close association of acute bacillary dysentery and the group of chronic diseases above mentioned appears to be too constant to be regarded as other than of etiologic significance.

THE HISTORY OF HOSPITALS, WITH SPECIAL REFERENCE TO SOME OF THE WORLD'S OLDEST INSTITUTIONS

By HENRY R. CARSTENS, M D , F A C P , *Detroit, Michigan*

AMONG the living institutions established by man, few have enjoyed a longer or more honorable history than hospitals. In very early documents, institutions are mentioned which may well be the prototypes of our modern hospitals. Such establishments were known in Ceylon, in India (for animals, as well as man), in Greece (in connection with some of the temples), and even in Ireland. With the exception of some of those in India, none are known to have existed for very long, at least not into the modern times.

As Christianity spread through Europe, a practical manifestation of its charitable teachings was the establishment of various institutions for the care of the pilgrim, the wayfarer, the aged, the ill, and the infirm. In mediæval times, their number increased rapidly, impetus being given to the movement by the Crusades (in the twelfth century), and by the spread of leprosy and the plague (in the twelfth to the fifteenth centuries). Limited though these establishments were, according to our modern standards, some of them attained a remarkably high efficiency for the times. Following the subsidence of the epidemics most of these institutions disappeared, and in general, hospital practice sank to rather low standards for many centuries until it rose to new heights during the past hundred years.

The word "hospital" is derived from the Latin, "hospitium"—a guest, as the institutions were first designed for the reception of wayfarers, pilgrims, and the infirm. Almost all were established by the church, although in England in later mediæval times they were often founded by private benefaction, and in Germany quite frequently as municipal undertakings. Even in these cases, they were usually placed under the direction of a local church or monastery.

The oldest hospitals still in existence are the Hôpitaux in Lyons and Paris, in France. Earliest mention is made of the Hôtel Dieu in Lyons in a manuscript of 580 A D, in which its establishment by Childebert is recorded. This is the oldest hospital which has continued in existence with the same name and the same purpose, its life having now spanned a period of almost fourteen centuries. A number of similar institutions were built in the seventh and eighth centuries at Poitiers, Verdun, Arles, Milan, and elsewhere, but their life was comparatively short. At about this time, leprosy commenced spreading through the European continent, and many institutions were established for the reception of lepers. The term "leprosy" was then a rather inclusive term, including probably a number of different diseases, such as lupus and scrofula, as well as leprosy. The lot of the leper

* Read at the Detroit meeting of the American College of Physicians, March 2, 1936

in those days was a hard one, outcast from society, bereft of all rights as a citizen, he had no means of making a livelihood. It was natural then to establish places for his care, although these were hardly hospitals, but really places for segregation.

Gradually these institutions tended to develop into different types, certain ones being designated for the care of the sick, the blind, the aged, orphans, lepers, etc. In the course of time the need for some of these became less, and those which are still existent usually belong to one of two general types, first, the almshouse for the care of the aged and indigent, and second, the hospital as defined in the modern sense.

The spread of hospitals was most rapid at the time of the Crusades, when large groups of individuals were moving by various routes to the Holy Land. Great encouragement to the foundation of hospitals was given by Innocent III, to whom is due the establishment of the Order of the Holy Ghost. In about the year 1204, the Pope founded the Ospedale di Santo Spirito at the old Tiber bridge in Rome. Hearing of the efficiency of the Hospital at Montpellier in France conducted by Guy de Montpellier, the Pope sent for him and entrusted him with the directorship of the Order of the Holy Ghost. Under Guy de Montpellier's guidance, the Order administered a tremendous number of hospitals throughout Europe either starting these as new institutions, or taking over the management of hospitals previously established. It has been estimated that almost two thousand were founded in Germany, and probably a greater number in France. A number of these still remain, although the Order gradually declined, being active now only in Italy. Other orders also participated in this movement, especially the Teutonic Order, the Johanniten, and the Order of the Lazarites, the last named devoting itself more particularly to the care of lepers. The brilliant history of the Order of St. John at the time of the Crusades is also noteworthy. The Hospital of St. John in Jerusalem (1099) had a high reputation as an institution of the first rank.

In Islam also, many hospitals were established during the time that the Arabians were spreading their culture through a rapidly extending territory. The Arabians' medical inspiration came largely from the Persian hospital in Djoundisabour (sixth century), at which many of them studied. Returning to their homes they founded institutions which were remarkably well organized for the times. A large number of these hospitals (called "bimaristans") were established at Bagdad, Damascus, Cairo, Aleppo, and elsewhere. There were often separate wards for the specialties (particularly ophthalmology and orthopedics), and provision was made for ambulant patients. A regular staff was in attendance, and the teaching of students was well organized.

In the course of time, there were many changes in fortune and development among the early institutions. The great majority have disappeared. Some have lost their buildings, and persist now only as endowments, or as place names, others have lived through the centuries. Some are very modest

and hardly worthy of their names. Others, proud of their heritage, are among the foremost European institutions. Some of these will be considered in the following paragraphs. The list does not pretend to be complete, it includes more particularly those which are of interest at the present time.

By way of comparison, it may be of interest to note that the western hemisphere has a number of hospitals which date back to early colonial times. The oldest of these is the Hospital of the Immaculate Conception in Mexico City, established in the early 1500's. In Canada, the oldest are the Hotel Dieu du Precieux Sang in Quebec (1639), and the Hotel Dieu de St. Joseph in Montreal (1644). In the United States, the first hospital founded as such was the Pennsylvania Hospital in Philadelphia (1751). There are a number which were established as almshouses or workhouses at an early date, the Philadelphia General Hospital (1751), Bellevue Hospital in New York (1735), the Charity Hospital in New Orleans (1736). These all became hospitals some decades later. In the Philippines, the Hospital de San Juan de Dios was founded in 1596 in Manila.

FRANCE

Although comparatively few of the ancient foundations of France are still in existence, the republic does boast of the two oldest of them all, the Hotel Dieu in Lyons, and the Hotel Dieu in Paris. The former was established by Childebert about the year 542 A.D., and has been conducted as a hospital ever since. Most of the buildings are comparatively modern (1737 to 1842). Surely a history of almost fourteen hundred years devoted to the care of the sick may well furnish an inspiration for us in modern times.

The Hotel Dieu in Paris has almost as ancient a history, which has been well told by Mackay. It was established about 652 A.D., as an institution for the care of the ill among the poor. Very early it showed a tendency to division into departments, being one of the first to establish a separate obstetrical department, a "Service d'accouchement" in the women's annex. In 1300, it is recorded that the hospital had an attending staff of physicians and surgeons. The obstetrical department was conducted by the *sages-femmes*. At this time it had grown to a capacity of eight or nine hundred patients, and probably reached double that size in the fifteenth century. The number of beds was actually much less, as it was the practice to use enormous beds for four to six patients each. Included in the hospital equipment were two bath tubs on wheels.

The Hotel St. Louis in Paris was established by Henry IV in 1607 for plague victims, it now receives cases of diseases of the skin. In 1260, Louis IX founded the Hospital des Quinze Vingts as a home for the blind. Its name indicates a capacity of 300 inmates, and is an interesting survival of the vigesimal system of counting. It is still in operation near the Place de la Bastille, part of its endowment consists of the land on which the Folies-Bergeres is situated.

(N D Photo)

FIG 2 L'Hotel Dieu, Beaune Founded 1443, building occupied 1452 (Arch du T C F)

One of the most charming old hospitals in France is the Hotel Dieu in Beaune. This was founded in the year 1443, and it is the oldest hospital which has continuously occupied its original building. The first patient was admitted January 1, 1452. There are some interesting remains of former hospitals scattered elsewhere through France. Partly in ruins, the "Grande Salle of the Hotel Dieu" at Tonnere is frequently visited on account of its architectural beauty. It was established by Margaret of Burgundy about 1293. In Angers the archaeological museum is housed in the old Hospital St. Jean, which was originally given to the city by an early Count of Anjou, Henry II, King of England (1133 to 1189).

HOLLAND AND BELGIUM

There are several medieval hospitals in Amsterdam and Delft in Holland. In Belgium, the Hospital of St. John in Bruges was established in the twelfth century, though few traces of its early buildings remain. It is still conducted as an active up-to-date institution. In the former chapter room are housed some of Memling's finest work (1430 to 1494). The Hospice de la Poterie in Bruges is an asylum for elderly women, founded in 1276. Damme, formerly the port of Bruges, possesses an old institution, the Hospital of St. John, a home for old persons.

ITALY

As the country in which Christianity first made its rapid spread, Italy boasts a number of early specimens. The oldest is the Santa Maria della Scala in Sienna, established in 898 A.D., with buildings dating largely from the fifteenth and sixteenth centuries. In Rome, the earliest was the Ospedale di Santo Spirito, founded in 1204 by Pope Innocent III, and shortly thereafter turned over by him to Guy de Montpelier as the first of the many conducted by the Order of the Holy Ghost. The buildings date from about fourteen hundred and later. Other old Roman institutions are the Ospedale della Consolazione, with parts dating from the thirteenth century, built on the site of an earlier hospital. The Ospedale di Santa Maria della Scala was established about the fourteenth century. These hospitals are still under the direction of the Order of the Holy Ghost. Other old hospitals in Rome are the Ospedale di San Giacomo, and the Ospedale di Giovanni. In Milan, the Ospedale Maggiore dates from 1456, and now serves as a city hospital. The City of Florence has many early survivals. Santa Maria Nuova was founded in 1287, by Falco Portinari (father of the supposed Beatrice of Dante), the buildings are largely seventeenth century. The Bonifazio (1377) has become an asylum for mental cases. San Giovanni di Dia was founded by Simone Vespucci about 1400.

One of the show places of Florence is the Ospedale de Santa Maria degli Innocenti, which was established as a foundlings hospital, and has served continuously as such up to the present time. The building was commenced

in 1421 after designs by Brunelleschi, and opened in 1444. Its history may be said to start much earlier, as there were combined with it the Hospitals of San Gallo (1218²), and Santa Maria della Scala (1316). For almost five hundred years, this institution has occupied its original building,

FIG 3 Ospedale Degli Innocenti, Florence. Founded 1421, building occupied 1444. The medallions of della Robbia may be seen at the heads of the Columns.

although the interior arrangements have been modernized from time to time. It is a treasure house of early Italian art, possessing many specimens of Ghirlandaio, della Robbia, Brunelleschi, Poccetti, and others. Best known of these are the famous medallions of the infants in swaddling-bands, by della Robbia. There are fourteen of different designs at the head of the columns on the front facade.

The infants were formerly put in a small door opening at one end of the portico, but now most of them are received from an affiliated maternity hospital nearby. Complete supervision is continued until maturity. The institution has always been a favorite charity of the city, though in recent

times the income from its endowment has been augmented by contributions from the municipality. The records of the hospital are practically complete from the date of its foundation, the name of the first infant received is said to have been Agathia.

FIG 4 Heiligen Geist Hospital, Luebeck (Ger Tour Info Office, N Y)

GERMANY

Hospital development in Germany took place largely in the thirteenth and fourteenth centuries through the activities of the Order of the Holy Ghost and the Order of the Lazarites. Vinchow differentiates between the hospitals established within the city walls and those established without the city walls. The latter were usually leper houses. He lists a large number of these establishments, some in even the smallest villages in Germany. It is probable that their total number was over 2000 at one time.

The best preserved examples that the writer has seen are the ones at Luebeck and Rothenburg o d Tauber. In the former city, the Hospital of the Holy Ghost has always been an almshouse for elderly people. Originally established in 1240, it has occupied its present site since the 1400's, and retains a part of its early buildings. This institution illustrates one phase in hospital development which was more common in Germany than elsewhere, in that it was established by the municipality. The Hospital of the Holy Ghost in Rothenburg was originally built outside one of the gates, but when the city extended its ramparts it was included within the walls.

FIG 5 Heiligen Geist Hospital Rothenburg O D Tauber Hospital to the right, city gate in the background

FIG 6 Heiligen Geist Hospital, Dinkelsbuehl Hospital to the right, city gate in the background (Ger Tour Info Office, N Y)

This is an excellent specimen of the small city hospital, the major part of its support now being derived from city funds. The main building dates from the fifteenth century.

Another Holy Ghost Hospital is to be found in the picturesque town of Dinkelsbuehl. It comprises both a home for old people and a hospital, the latter housed in a new building erected in 1864. Additional examples of old hospitals still exist in Nuernberg, Wuerzburg, Luneberg, and in Bremen (St. Georgen Hospital, originally founded as a leper house). In Berlin, a Hospital of the Holy Ghost was built about 1278, but it has entirely disappeared, although there is an endowment remaining which is used for charitable purposes. St. Gertrauden Hospital was founded in the early 1400's "without the walls" on the square called "Spittelmarkt" at the east end of Leipzigerstrasse. It has recently been moved to a new location.

ENGLAND

The first hospital recorded in England was built in York in Saxon times, 937 A.D. After the Conquest, many more were founded. They all suffered severely at the time of the Reformation, though a large number were preserved through the contributions of wealthy citizens. Those that had been founded as lay endowments continued their functions, for such philanthropy was a favorite form of charity by the well-to-do in the fifteenth and sixteenth centuries. Only the institutions in London were hospitals for the sick, those in the small communities were almost invariably of the almshouse type.

Of the hospitals, the most famous is St. Bartholomew's in London, which recently celebrated its 800th anniversary, having been established by Rahere in 1123. This one is well known to many physicians, as it is one of the great centers of medical teaching in the world. Its buildings date from 1760 and later. St. Thomas Hospital comes next in age (1215). St. Mary of Bethlehem was founded for the care of mental cases in 1247 (from its name was derived the word "bedlam").

In numerous towns and villages of provincial England there will be found near the parish church a small building which is the almshouse. These institutions are of varied character as regards the nature of their endowments and the purpose for which they are now conducted. The original endowment usually was in the form of land, and naturally these endowments have been subjected to the vicissitudes of prosperity and depression for many centuries. Sometimes the institution owned the land outright, sometimes it was given a certain allowance from an estate. Certain of these almshouses were founded for the care of a number of old men, or old women, or for couples only. Charming examples are to be found in Canterbury, Sherborne, Burford, Norwich, Chipping Campden, Abington, Exeter, and in innumerable other communities.

Of this group the most perfect architectural specimen is the Hospital of

St Cross at Winchester It was established by Bishop Henry of Blois (a nephew of William the Conqueror) in 1123. It is housed in a double quadrangle of buildings which represent various gifts and additions from Norman times and later. Most of the quarters were built by Cardinal Beaufort in the sixteenth century. It is of the almshouse type providing a home

FIG 7 St Bartholomew's Hospital, London. Founded 1123 A.D. Buildings 1760 and later. (Photocrom Co. Ltd.)

for old men, and in addition (as a separate foundation) affords a home for 12 men of "gentle breeding." Its endowment also provides for the "wayfarer's dole," consisting of a pint of beer and some bread, which any wayfarer may have for the asking.

In other countries, there are a number of survivals. Of the many founded by the Arabians, there are several still in existence. The famous Bimaristan El Mansouri in Cairo, commonly called by the name of its founder, Qalaoun (1284), is now devoted exclusively to ophthalmological cases. A new addition to it was constructed about twenty years ago. One of the hospitals in Aleppo dates back to 1344 A.D.

In Spain, the Moors built a number of institutions during the time of their occupation (Cadiz, Seville, Toledo, etc.). The General Hospital in Madrid traces its foundation to three Moorish hospitals which were combined by Phillip II in 1566. There are a number of post-Moorish hospitals

and almshouses dating from the thirteenth to the sixteenth centuries in some of the other cities in Spain

In this brief outline of the history of hospitals it has not been possible to discuss many of the interesting phases in their early development, nor to do more than make brief mention of a few of the hospitals which have been in existence for many centuries. Rich in historical and medical interest, as well as in architectural beauty, many of these institutions are well worth a visit by the physician traveling abroad

CASE REPORTS

AN UNUSUAL CASE OF OSTEOPSATHYROSIS (FRAGILITAS OSSIIUM, LOBSTEIN'S DISEASE) *

By EVERETT B POOLE, M D *Greenville South Carolina*

THE disease which has been called fragilitas ossium, Lobstein's disease,¹ or osteopsathyrosis is characterized by the remarkable symptomatic triad of blue sclerae, brittle bones and deafness. The general features of the disease have been well summarized by Apert,² and by Ottley,³ who give comprehensive reviews of the literature. Ottley lists the following as characterizing the syndrome of osteopsathyrosis:

- 1 Fragility of bone
- 2 Peculiar conformation and structure of bone
- 3 Peculiar shape of the skull
- 4 Laxity of the ligaments
- 5 Blue coloration of the sclerae
- 6 Deafness
- 7 Abnormal electrical reaction of the muscles
- 8 Miscellaneous abnormalities of the teeth, nails and hair and disturbances of the vasomotor system
- 9 Familial character of the disease

Brief comments on these peculiarities may help to delineate the clinical picture more clearly.

1 The bones fracture as the result of injuries so slight that they are often described as "spontaneous fractures." This is not due to a deficiency in calcium content, but is to be ascribed to morphological defects in the architecture of the bones.⁴ The normal calcium-phosphorus ratio of the blood is not disturbed.

2 Changes, seen more distinctly in the long bones, comprise extreme slenderness, incurving of the shaft, most marked in its middle portion, thinning of the cortex and increased transparency to roentgen-rays. The epiphyses show no characteristic change.

3 The occipital prominence of the skull is exaggerated, and there is bulging of the temporal bones. The general effect is as if the entire skull had been subjected to powerful downward pressure on the vertex.

4 The ligaments show a remarkable degree of relaxation. As a consequence pes planus, hyperextensibility of the fingers and knees, and frequent sprains and dislocations are observed.

5 Blue sclerae constitute a very striking feature of the syndrome, though by no means pathognomonic. They do occur in individuals who show no evidence of osteopsathyrosis. The blue color is not due to a deposit of pigment in the

* Received for publication January 3, 1936.

From The Department of Medicine, Duke University Hospital and School of Medicine.

sclerae but rather to scleral thinness and transparency which permit the choroidal pigment to be seen

6 It is probable that the relaxation of the ligaments of the bones of the middle ear is responsible for the deafness so frequently reported,² though labyrinthine⁵ and osteosclerotic⁶ deafness have been described

7 Upon electrical stimulation an incomplete reaction of degeneration is seen

8 Thinness and fragility of the hair and translucency of the teeth ascribed to a deficiency in enamel have been noted. Subjects of the disease are said to be especially liable to migraine and vasomotor disturbances of various types

9 The disease has repeatedly been observed in several generations. Apeit concludes that the malady is inherited in the manner of a Mendelian dominant character. There is a wide variation in the distinctive features in individual cases which may display any or all of them. Deafness, fragility of bone, or any other feature may be inconspicuous or absent in any given case.³ Blue sclerae may be the only apparent abnormality.⁷ Francke⁸ is of the opinion that the complete syndrome (blue sclerae, deafness, fragile bones) is found only in individuals whose parents have also shown it

In the light of the foregoing brief description of osteopsathyrosis the following case is reported

CASE REPORT

Luther C, a white male, aged 30, congenitally defective vision, blue sclerae, marked relaxation of ligaments producing pes planus and hypermobility of joints, blood chemistry normal, no fragility of bones

The patient entered the hospital on February 7, 1934, complaining of pain in the head and eyes of two years' duration

His father, mother and sister (the only sibling) were seen, and they state that no other member of the family has had any disease similar to that from which the patient is suffering. The parents state that the patient was not cyanotic at birth, nor could any evidence of rickets in childhood be obtained

Since birth the patient's sight has been exceedingly poor, and he was almost completely blind in childhood with some improvement as he became older. He was also born with a marked deformity of the left chest wall. As long as he can remember he has noted very marked looseness of all the joints, especially those of the knees and ankles. He has always had flat feet. Two years ago the right cornea was severely injured by a foreign body, reducing the very poor vision of the eye to a bare perception of light. All useful vision remaining exists in the left eye, where he can see only the gross outlines of objects

The patient presents a truly remarkable appearance (figure 1). He is very tall and thin with red hair and sharply contrasting indigo-blue sclerae. He looks older than his stated age of 30. The face is unusually long with a beak-like aquiline nose. The scapulae and acromial processes are very prominent, and there is marked anterior angulation of the left chest at the costo-chondral junction, producing a pigeon-breasted appearance

The extremities are unusually long, the hands flattened, and, owing to a remarkable grade of ligamentous relaxation, the tarsal bones (figure 2) have moved downward to such an extent that they lie at a lower level than the rest of the foot, being covered by a mass of hyperkeratotic skin. The joints everywhere show an extreme degree of relaxation and hypermobility. This is especially marked in the fingers, shoulder joints and knees

FIG 1 General appearance of patient

FIG 2 Showing marked relaxation of the ligaments of the knees and feet

The eyes show several noteworthy deviations from the normal (figure 3). The sclerae are really blue, not bluish. There are frequent nystagmoid jerks of the eye-balls, and it is then observed that the iris moves backward and forward in a wavy fashion as though having no anchorage from behind. No lens can be seen in either eye. The eyes show a definite divergent strabismus, and lateral movements cause nystagmoid jerkings. There is no evidence of injury to other cranial nerves except slight bilateral deafness by the audiometer test. Using air conduction, there was a loss of around 20 sensation units for both ears at all frequencies.

The lungs are negative, and the heart is not enlarged. There is a harsh systolic blow at the apex. The abdomen, genitalia and rectum show no abnormalities. The tendon reflexes in the upper extremities could not be obtained but are sluggish and equal in the lower extremities. Abdominals are present, Babinski bilaterally negative. No disturbance of sensation.

FIG 3 Showing appearance of eyes. Partial iridectomy has been performed.

Very exhaustive accessory clinical examinations were made. Blood studies, gastric analyses, kidney examinations, sedimentation tests, stool examinations, spinal fluid studies, etc., all gave normal findings. Complete blood chemistry studies in the laboratory of Dr. W. A. Perlzweig revealed no noteworthy deviation from the normal. The serum calcium and phosphorus were within normal limits on three examinations.

Numerous roentgen-ray studies were made, but, except for the malformations noted above, nothing abnormal in the bones was found. There was no marked decalcification anywhere.

Biopsy sections from a ligament of the foot (cuneonavicular) were made, and although there appeared to be looseness of the collagenous fibers as compared to similar normal tissue prepared in the same way, findings were not sufficiently striking to justify serious consideration.

The condition of the eyes was diagnosed by Dr. Banks Anderson as ectopia lentis. Both eyes were operated upon and later on maximum correction established, but the end result was poor, vision with the best possible correction being 15/200 in the left and 10/200 in the right eye.

SUMMARY AND DISCUSSION

A case is presented showing three of the cardinal features of osteopsathyrosis (Lobstein's disease, fragilitas ossium), but with no history or other evidence of bone fracture. The blue sclerae, defective ligaments and slight deafness (together with the finding of ectopia lentis) can all be explained by a congenital defect in the structure of fibrous tissue forming the sclerae, ligaments and tendons.

 ORTHOSTATIC HYPOTENSION, REPORT OF A CASE

By WANN LANGSTON, M.D., F.A.C.P.,
Oklahoma City, Oklahoma

IN 1926 Biadbuay and Eggleston¹ reported three cases of a syndrome, the outstanding characteristics of which were "the occurrence of syncopal attacks after or during exertion or even after standing erect for some minutes. Other features in the three patients are a slow, unchanging pulse rate, incapacity to perspire, a lowered basal metabolism and signs of slight and indefinite changes in the nervous system. Each of these patients felt much worse during the heat of summer." Other symptoms were increased urinary output when patients were in recumbent position, youthful appearance, and loss of sexual desire and power. A slight increase in blood nitrogen and lessened phthalein output when patients were up and active were also noted.

The most outstanding characteristic in all these cases was the abrupt drop in blood pressure when the patient changed from a recumbent to a vertical position. This drop involved both the systolic and diastolic pressures, the extreme figures being a drop in case 1 from 105 systolic and 60 diastolic supine to 40 systolic and 28 diastolic standing, in case 2 from 158 systolic and 108 diastolic to 52 systolic and 40 diastolic, and in case 3 from 84 systolic and 60 diastolic to 45 systolic and 25 diastolic. It was noted that the pulse rate was relatively slow and remained approximately the same even when the blood pressure sank to critical levels.

* Received for publication October 15, 1935

They designated this syndrome as "Postural Hypotension"

In 1928 Ghrist and Brown² reported two cases of this condition, Ashworth³ two in 1929, Reicke and Upjohn⁴ one in 1930, Barker and Coleman⁵ one in 1931, and Sanders⁶ one in 1931. In 1932 Laubry and Doumer⁷ reported five cases, two of which have been questioned as not representing the characteristic syndrome,⁸ and suggested the term "Orthostatic Hypotension" as being more descriptive than the one previously used. Barker⁸ reported an additional case in 1933, Allen and Magee⁹ one in 1934, Croll and Duthie¹⁰ one, the first in Great Britain, in 1935, Weis¹¹ one in February 1935, and in July of this year Alvarez and Roth¹² reported the eighteenth case (if we exclude the two questionable cases of Laubry and Doumer) thus emphasizing the rarity of the condition or, what is more probable, the infrequency of its recognition.

The normal reactions of blood pressure and pulse rate to postural change have been studied by many investigators. In general, on changing from a horizontal to a vertical position there is slight elevation or depression in the systolic pressure, a definite rise of about 10 millimeters in the diastolic pressure, resulting in a lowered pulse pressure and a definite increase in pulse rate amounting to 10 or more beats per minute.

REPORT OF CASE

History C. W., a white male, school teacher, aged 56, was of Irish-Dutch extraction, of a family noted for longevity, the second of a family of nine children all of whom are living except two, an all-round college athlete (football, baseball, track and tennis) actively engaged in athletics up to the age of 45. He had always been healthy until the onset of the present condition except for minor ailments and except for a ligneous abscess behind the right ear at the age of 30 and an attack of iritis of the left eye at 39.

In August 1928, he was first troubled with frequent urination at night. Several doctors reported a few pus cells in the urine. He had several teeth extracted (one ulcerated) without relief. In October the urinary disturbance became more pronounced. In April 1934, he passed a large rough stone, preceded by passage of bloody mucous in urine. From 1928 to 1934 he drank artesian water of high mineral content. Prior to this time he had always perspired freely, but during this period it gradually ceased, and he perspired only from mid-chest up. Perspiration gradually ceased almost completely until the spring of this year when he perspired somewhat more freely. He did not note that he was particularly intolerant to hot weather.

In the fall of 1934 he noted a burning sensation across the abdomen, extending down to the feet and corresponding roughly to the area of anhidrosis. In January 1935, he had an attack of influenza, and after this the burning sensation mentioned above ceased and, as the weather became warmer, he began to perspire more freely.

About three years ago he began to note muscular weakness and fatigue about the hips. At first this was intermittent. He also noticed a similar weakness in the arms but much less marked, the symptom disappearing quickly with rest. About this time he began to "stoop" or "hump over" in walking, and his friends would tell him to "straighten up." A little later he would become very tired through the hips after walking a block or two, finding it necessary to rest after slight exertion. At the time he attributed this to the fact that he had sustained a fracture of the hip at football. Soon this localized fatigue became general all over the body and progressively worse, until now he experiences profound fatigue, giddiness and almost faints on changing from reclining to upright position, walking, and particularly on standing still for a few moments. Associated are fatigue and cramping in the muscles of the

legs, arms and neck. The muscles of the neck became so weak he could scarcely hold his head up, and this has become one of the most pronounced symptoms. The vocal cords would become fatigued and the voice husky and uncontrollable. The muscles of the arms seem too weak to lift any weight. These symptoms are most pronounced when he is standing, are relieved somewhat when he sits down, and he experiences prompt and almost complete relief when he lies down.

More recently he has experienced blurring of vision when standing or after exercise, promptly relieved by sitting down, bending forward or reclining.

He has noticed coldness of lower extremities below the knee for the past year, and since last winter he has noticed swelling of the feet and ankles. This has lately disappeared. There has been some numbness and tingling.

He passes very little urine during the day when he is up and around, but has nocturnal frequency and polyuria. Actual test after treatment was under way showed 12.5 ounces for the 14.5 waking hours, and 20 ounces for the 9.5 sleeping hours.

He has developed nervousness, a coarse tremor of the hands, and more or less mental sluggishness. He has also developed peculiar involuntary movements resembling laughter. This is more pronounced when he is weakest. He has also developed some emotionalism. There has been loss of sexual desire and potentia.

He came to me first on August 2, 1935, with this story and the diagnosis of heart trouble and low blood pressure.

Examination, August 2, 1935. A well developed and well nourished middle-aged white man, apparently not as old as stated age. Temperature 99.2° F, pulse 84, blood pressure reclining 120 systolic and 80 diastolic. There is no apparent anemia, cyanosis, jaundice, edema, dyspnea or distress. The face is rather florid, the beard somewhat thinner than in the average man, the hair graying, and a tendency to baldness. The eyes, ears, nose, mouth, teeth, tongue and pharynx show no significant changes. The thyroid is not enlarged and there is no cervical adenopathy.

Heart shows slight enlargement to the left. There are no murmurs or abnormal accentuations. The heart tones are normal. Lungs. No abnormal findings. Chest wall. No abnormality. Abdomen. No abnormality noted. The liver and spleen are not palpable. No areas of tenderness, and no masses to be felt. Genitalia. No abnormality found. Rectal. Negative findings. Neuro-muscular system. The musculature is apparently normal. There is a definite coarse tremor of the fingers, more marked in the left hand. Tendon and superficial reflexes normal. Pupillary reactions are also normal. Integument. The skin is soft and pliable. There are no evidences of pigmentation. There is no obvious perspiration.

Blood. hemoglobin 90 per cent Sahli, red blood cells 4,510,000, white blood cells 6,100. N 67 per cent, L 33 per cent. Sugar tolerance after 100 grams of glucose, 80-150-125 mg. Wassermann and Kahn negative. NPN 510 mg. Urea N, 26.7 mg. Phthalein output reduced, although he collapsed and voided involuntarily 20 minutes after intravenous administration of the dye. For the balance of the two hours the elimination was 25 per cent.

As stated above, the blood pressure at the first examination was 120 systolic and 80 diastolic with patient in recumbent position. Upon sitting up an immediate drop to 95 systolic and 70 diastolic was noted. The following day I rechecked the blood pressure and found the following: recumbent, 125 systolic and 80 diastolic, sitting, 90 systolic and 60 diastolic, standing, 60 systolic and 7 diastolic, with weakness and syncope. During these observations the pulse rate was around 80, and varied scarcely at all from this figure, even when pressure went to extreme low levels. I have made many blood pressure observations always with the same general results, namely, a marked drop in both systolic and diastolic pressures upon changing from horizontal to vertical positions, with little or no change in the pulse rate. Typical are the observations made on August 28, 1935, and checked with Dr. W. F. Keller. (Figure 1.)

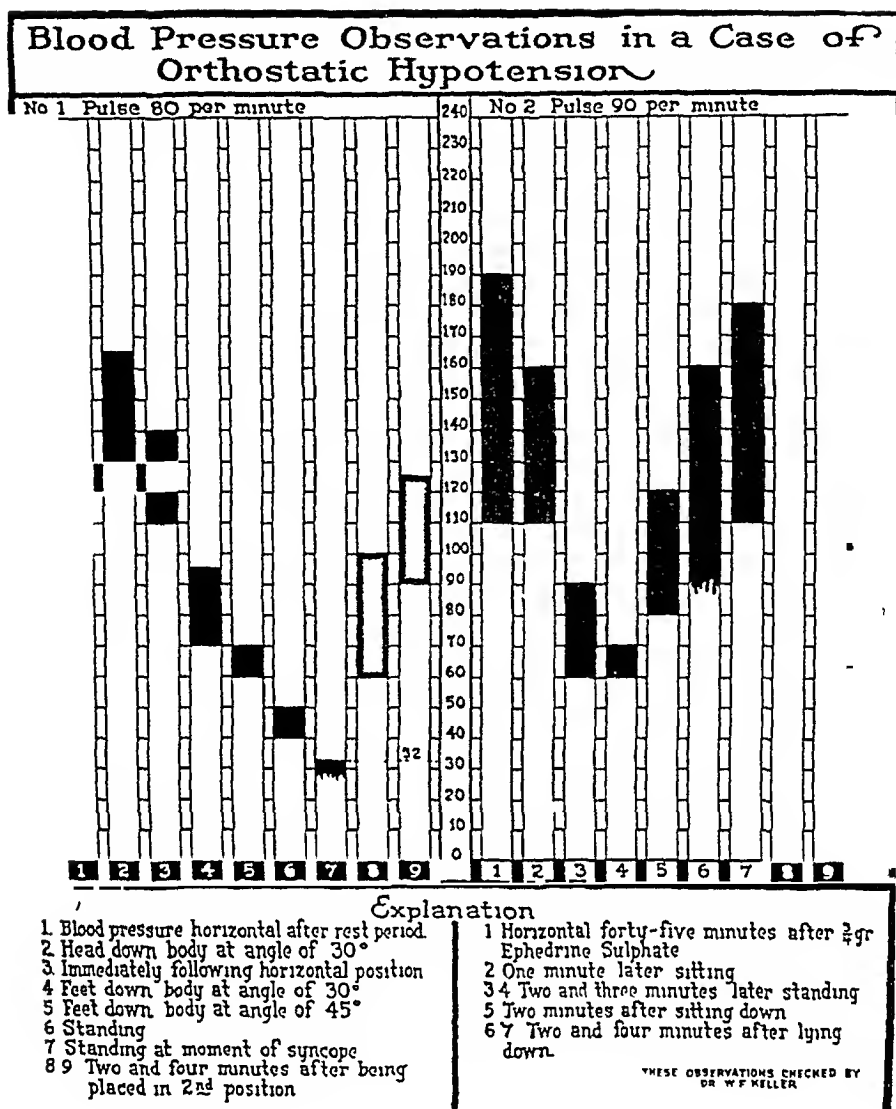

FIG 1

The following observation noted on different occasions, to me is unique and perhaps important. During attacks of great weakness the patient has involuntary paroxysms exactly simulating laughter, during which he chuckles and manifests the typical contractions of the abdominal muscles, but he feels no desire to laugh and the facies indicates no emotion of amusement. When a normal individual laughs the blood pressure is raised, when this man has such a paroxysm his pressure is raised. Ghrist and Brown in one of their cases noted what may be an analogous phenomenon, namely, clonic convulsions just preceding syncope, explained by the patient as being voluntary muscular contractions in an effort to stand.

To summarize the case. An apparently healthy middle-aged man presents certain definite subjective and objective findings, namely, orthostatic drop in both systolic and diastolic pressures without compensatory increase in pulse rate,

orthostatic weakness, giddiness and syncope, orthostatic oliguria, increase in blood urea nitrogen, with reduced phthalein output, hypohidrosis with geographic distribution, loss of libido and potentia, nervousness, tremor, and involuntary convulsive paroxysms resembling laughter when very weak—all of the characteristic findings of the syndrome designated as orthostatic hypotension.

An analysis of the cases thus far reported is shown in the following table. This reveals orthostatic hypotension and orthostatic weakness, giddiness and

SIGNIFICANT FINDINGS IN CASES REPORTED

Symptoms

Symptom	Positive	Negative	Doubtful	This case
Orthostatic severe syncope	11	7	0	+
Orthostatic weakness or mild syncope	17	1	0	+
Orthostatic oliguria	10	0	8	+
Anhidrosis or hypohidrosis	10	3	5	+
Intolerance to hot weather	4	2	12	0
Loss of libido and potentia	3	5	10	+

Physical and Laboratory Findings

Finding	Positive	Negative	Doubtful	This case
Orthostatic hypotension	18	0	0	+
Slow or unchanging pulse rate with changing position	12	4	2	+
Lowered metabolic rate	10	2	6	?
Increased blood urea nitrogen	7	0	11	+
Youthful appearance	4	7	7	+
Slight anemia	5	6	7	0

syncope as invariable phenomena, and lack of compensatory tachycardia, lowered metabolic rate, nitrogen retention, and orthostatic oliguria, as almost invariable.

In addition to the above practically constant findings, others of greater or less significance are changes in the pupillary reactions, and other neurological changes, insomnia, weight loss, dyspnea, geographic anhidrosis, etc.

Bradbury and Eggleston found that the administration of epinephrine was followed by an increase in systolic and pulse pressures and in pulse rate, but that the diastolic pressure was not materially affected. They concluded that epinephrine did not cause vaso-constriction in these cases. Atropine caused dryness of the mouth and flushing of the skin in two cases, but no increase in

pulse rate. Pilocarpine caused salivation and sweating in two cases. In general, these observations have been confirmed by other investigators. Bradbury and Eggleston conclude that "paralysis of the sympathetic vaso-constrictor endings seems to be the only adequate explanation of the blood pressure reactions in these three cases. It accounts for the absence of vaso-constriction following the injection of epinephrine and it explains the total absence of the normal vasomotor control by which blood pressure is maintained at a nearly constant level in the face of changes in the position of the body in normal persons." In general, these conclusions have been concurred in by subsequent authors. Ghrist and Brown thought that "the essential disturbance in this disease is lack of resistance in the splanchnic vessels to shifts in the blood mass and absent or diminished vagus regulation of the heart rate to changes in blood pressure. The opinion is advanced that this disease represents a hypotonic state of the myoneural structures of the sympathetic and parasympathetic nervous system of unknown origin." Barker explains these phenomena 'by loss of reflex posture or orthostatic vaso-constriction necessary to maintain normal blood pressure against the force of gravity and by loss of reflex acceleration of the cardiac rate.' He attributes the accelerator effect of epinephrine and ephedrine in these cases to their direct effect on the heart muscle. Alvarez and Roth believe the essential pathological physiology is in the "sympathetic control of the caliber of the vessels in the abdomen."

Prof J. A. MacWilliam, who studied the case of Croll and Duthie, found that in normal individuals "the slower heart rate in the horizontal posture, as compared with the sitting is essentially due to the action of the carotid sinus reflex, while the quicker rate in standing than in sitting is mediated through afferent impulses from the lower limbs which are also concerned in the maintenance of the compensatory adjustments (vaso-constriction in the splanchnic area and elsewhere) involved in keeping up the aortic pressure in the erect posture." He believes that "both pulse rate and blood pressure adjustments in the standing posture are influenced by afferent impulses from the lower limbs, apparently originating in some part of the vascular circuit in these limbs," and that in these cases there is a disturbance of this mechanism, an opinion that seems to be refuted by Alvarez who points out that while orthostatic hypotension is not produced by lumbar sympathectomy, it is produced for a time by anterior rhizotomy.

Alvarez and Roth also found that epinephrine intravenously did not cause peripheral vaso-constriction, although it did cause elevation of pulse rate and systolic blood pressure. The fact that atropine does not cause increase in pulse rate in these cases suggests interference with the normal sympathetic accelerator mechanism of the heart. On the other hand the sympathetic supply to the sweat glands is intact if depressed since the reaction to pilocarpine is present to an extent at least.

The effects of various therapeutic agents have been observed. Epinephrine, in addition to raising the systolic pressure and pulse rate, gave temporary symptomatic relief. Thyroxine gave questionable relief in the work of Bradbury and Eggleston. The use of a tight abdominal binder has given variable results in different patients. Ghrist and Brown first noted the beneficial effects of ephedrine. Barker, and later Allen and White noted improvement from ephedamine tartrate, but the disagreeable symptoms seemed to more than counterbalance the

benefits. Various other remedies have been tried, but to date ephedrine sulphate seems to have given most consistent and lasting improvement subjectively and objectively.

Having noted the beneficial effects of suprarenal cortical hormone (eschatin) in a case of Addison's disease with orthostatic hypotension (secondary), I decided to try this remedy with my patient, and accordingly on August 3, I gave him 1 cc intramuscularly and he reported that within an hour or two he felt stronger. I repeated this on August 4, omitted it on the fifth, and on the morning of the sixth he collapsed in the elevator on his way to my office. I gave him 5 cc of eschatin immediately and within 30 minutes the blood pressure was 150 systolic and 100 diastolic, with patient recumbent. The following day he was feeling better, the blood pressure being 160 systolic and 100 diastolic reclining and 120 systolic and 80 diastolic sitting, in the forenoon, and in the afternoon, after some walking during the interval, 125 systolic and 90 diastolic sitting. I did not repeat the eschatin on this date.

On the morning of August 8 he took $3/8$ gr ephedrine sulphate and reported to the office at 9 00 o'clock. At this time his pressure was 120 systolic and 80 diastolic reclining, and 90 systolic and 60 diastolic sitting. I gave 0.25 cc eschatin and in 20 minutes the reading was 150 systolic and 100 diastolic, reclining. On the ninth he received 0.25 cc and on the tenth when he reported the pressure was 90 systolic and 60 diastolic, and he complained of weakness. I gave him 0.5 cc with only slight improvement. From August 10 to August 21 he took $1/3$ cc eschatin and $3/4$ gr ephedrine sulphate daily and though his condition was better than before he began treatment, it was far from being satisfactory. He noted that the ephedrine invariably caused increased pulse rate, heart consciousness and nervousness. He reported on the twenty-first, with the following blood pressure: 125 systolic and 80 diastolic, reclining, 90 systolic and 60 diastolic, sitting. At 3 00 o'clock p.m. it was 100 systolic and 70 diastolic and 60 systolic and 40 diastolic. I gave him 0.5 cc eschatin and in 30 minutes the pressure was 140 systolic and 90 diastolic, and 100 systolic and 60 diastolic sitting. From the twenty-first to the twenty-seventh, ephedrine was omitted and 0.5 cc eschatin twice daily was administered. He was fairly comfortable during this period but experienced considerable weakness. He reported on August 28 when the series of observations charted was made.

From August 28 to September 3 he took ephedrine and amylal three times a day, but the cumulative effect of the amylal was too disturbing. I then outlined a course of procedure whereby he took one-half grain of ephedrine before getting up in the morning and one-fourth grain every four hours during the day. He felt, however, that the larger dose in the morning was unnecessary, he has settled down to three or four one-quarter grain doses daily, and his condition has been much more satisfactory.

Although Weis has reported a case as cured by this therapy, and his observations over a considerable period of time seem to substantiate it, it seems too much to expect a cure in this case, although one hopes to make life livable for him.

Weakness, dizziness, faintness, a tendency to syncope on suddenly changing from a reclining to an upright posture or upon standing still for a few moments, are not uncommon complaints. If every such case were carefully considered and blood pressure readings made in both positions, it is entirely possible that many other cases might be recognized. In view of the frequency of anhidrosis or hypohidrosis in these cases, all patients complaining of this symptom should be investigated with this entity in mind.

One occasionally sees individuals, usually of a definite ptotic type with low blood pressure, who have been improved apparently by the use of a tight abdominal binder. Improvement is not due to replacement of the abdominal viscera, for some of us have demonstrated with the fluoroscope that this does not occur in spite of the symptomatic improvement. A study of this case and of the reports of others leads one to believe that any such benefits come from forcing the blood out of the splanchnic area, and that in all probability in some of the cases at least the symptoms are due to splanchnic vascular atonicity.

Certain acute processes, notably influenza, affect blood pressure. Is it not probable that some of the profound debility in influenza may be on the same basis?

SUMMARY

1 There appears to be a definite entity with characteristic findings which may be properly designated as orthostatic hypotension.

2 The chief characteristics are orthostatic hypotension, orthostatic weakness or syncope, absence of compensatory tachycardia on rising from reclining to upright position, orthostatic oliguria with nitrogen retention and decreased phthalin output.

3 The syndrome seems to be on a basis of sympathetic nerve ending impairment.

4 The literature has been reviewed briefly.

5 Eighteen cases have been reported previously and another is presented here.

6 To date ephedrine sulphate has given most consistent benefit.

COMPLETE HEART BLOCK FROM SCLEROSIS OF THE BUNDLE OF HIS

By BEN R HENINGER, M D, F A C P, and K L DICKENS, M S, M B,
New Orleans, Louisiana

COMPLETE heart block may result from various types of lesions involving the bundle of His or other parts of the conduction system. Most of the cases of complete heart block reported in the literature were the result of syphilitic gummas. There are on record isolated cases of heart block in which fatty infiltrations have caused auricular-ventricular dissociation, in others, tumors, such as endotheliomas and sarcomas, have been found to destroy the conduction pathways of the bundle. On the other hand, there are numerous cases in which there was clinical heart block, but at autopsy no lesion was found in the bundle of His.

In a recent paper, Yater and Cornell supply evidence which indicates that heart block may be due to calcareous lesions involving the bundle of His, as well as the subendothelial surface of the heart. Yater further states that this specific form of lesion producing complete heart block must be rare, as he could find only 47 cases which have been sufficiently studied and in which the criteria fulfilled the requirements for this diagnosis. It is possible that this condition may be much more frequent than the literature leads one to believe. On account of the rarity of complete heart block due to calcareous disease of the bundle of His, we present this report with the hope that it may stimulate a search for similar cases.

CASE REPORT

Case History An unemployed Italian male, aged 62, was admitted to Touro Infirmary, on the service of Dr Emile Block, June 3, 1934 and died June 9, 1934. The patient was referred to one of us (B R H) within 20 hours after admission, with a history that his present illness started three weeks previously. Predominating symptoms were marked dyspnea, swelling of the ankles, and inability to sleep at night. All symptoms were progressive in character until the occurrence of abdominal swelling, which had been present for one week. During this period there was precordial pain, running down the arms, later there was a productive cough.

Physical Examination Examination revealed a well-developed male, of large frame, with moderate cyanosis and generalized edema. Dyspnea was unusually marked. The heart was markedly enlarged to the left. The apex impulse was easily seen and felt at the anterior axillary line on the left side. The right border extended outward about 5 cm from the median line in the third interspace. The cardiohepatic angle could not be made out, the impression was gained that there was a pericardial effusion, although the classical signs were absent. The heart sounds were feeble, especially at the apex, while at the base they were more easily audible. The pulse and heart rate, while the patient was lying down, was 30 per minute. The peripheral vessels were moderately sclerosed. The blood pressure was equal on both sides, being 215 systolic and 110 diastolic. The lungs showed fine crepitations at both bases. The liver was markedly enlarged downward and very tender. There was free fluid in the abdomen as shown by shifting dullness.

* Received for publication October 5, 1935.

From the Departments of Medicine and Anatomy, Louisiana State University Medical Center, New Orleans, La.

Our impression of the case was atherosclerotic type of heart disease with hypertension, congestive heart failure, complete heart block, and general anasarca.

An electrocardiogram taken shortly after entrance into the hospital (figure 1) revealed heart block of high grade, with infrequent ventricular extrasystoles. A

FIG 1

second cardiogram taken 6/5/34 revealed about the same picture, the ventricular rate in both was 30 to 45 per minute.

Progress Notes The patient was placed on the conventional treatment for congestive heart failure, including limitation of fluids, a salt-poor diet, and digalein, 2 cat units every four hours for a period of three days, totaling 24 cat units. Following this digitalization, there seemed to be definite improvement, the area of cardiac dullness apparently diminished, there was less orthopnea, and the mental attitude of the patient was very noticeably improved. Following the discontinuance of digitalis the apparent improvement was maintained for about 30 hours, but then the dyspnea returned in even more marked degree. With this, the patient seemed to develop mental disturbances, in that he was unwilling to remain in the hospital. Finally, smothering spells became so distressing that the patient could hardly be kept in bed. Morphine with atropine was given hypodermically without much benefit. Suddenly, while the patient was sitting up in bed, he developed convulsive seizures. The pulse varied from 28 to nearly 50 per minute. Barium chloride, gr 1 every three hours, was given for the next 24 hours, but in spite of this, repeated convulsions ensued, lasting for variable periods of time. The patient died suddenly on the morning of June 9, 1934.

Pathological Examination Gross Examination of the Heart and Pericardium. The pericardium was smooth and glistening. There were approximately 75 cc of clear amber-colored fluid in the pericardial sac. The heart weighed 460 grams and showed hypertrophy of the left ventricle. There was a moderate amount of fatty infiltration evident beneath the epicardial surface. The organ was removed and

sectioned. The myocardium was reddish-brown in color and measured 3 cm in thickness. Scattered throughout it were areas of degeneration. The endocardium was pinkish-gray in color, smooth and glistening in appearance. The foramen ovale was closed. All valves were competent. The ostia of the coronary arteries were patent, however, upon tracing the arteries they were markedly sclerotic. The in-

FIG 2 View of left ventricle and aorta. Calcium mass (C) shown diagrammatically in approximate position after blocks in area, B, have been taken out. Area S indicates where a further section was removed for study of the muscular septum. Arrow points to the right coronary artery orifice.

timal surface of the aorta was pinkish-yellow in color, with many arteriosclerotic plaques scattered throughout.

Histopathologic Examination of the Heart Two blocks of tissue were removed from the heart at the junction of the membranous and muscular septum. These blocks were taken so as to include an area from the bases of the right and left anterior aortic valves to within about 1 cm of the muscular septum of the heart. Microscopic sections were taken at various intervals so as to determine the length and distribution of the fibro-calcareous mass, A-V bundle and its branches. Figure 2 shows the opened left ventricle and aorta with area from which the blocks for examination were taken. An additional section was taken from the muscular septum for study of the A-V bundle and its branches. The arrow points to the right coronary artery, thus giving exact anatomical location of the blocks. The approximate location of the calcareous mass is indicated diagrammatically.

The tissues were partially decalcified and sections cut at 10 micra. The sections were stained with hematoxylin and eosin and with Mallory's connective tissue stain. Sections were taken from various regions and approximate length of the mass was ascertained. Figure 3 reveals the position of the mass and its characteristic nature. Figure 4 is a higher magnification of a portion of figure 3.

FIG 3 Low magnification of membranous and muscular septum revealing the exact position of the calcium mass. *RA* is right auricle, *A-V* indicates the atrio-ventricular bundle, *C* indicates the two calcium masses with small particles of the homogeneous substance scattered between. An edge of the aortic cusp is shown above. *S* indicates the muscular portion of the septum. (45 \times mag.)

A calcareous mass was revealed at the junction of the membranous and muscular septum in the myocardial portion, which was surrounded by dense fibrous connective tissue. Near the center of the mass this fibrous connective tissue separated the cal-

FIG 4 Reveals a higher magnification of portion of mass and A-V bundle as shown in figure 3. C indicates the calcium mass surrounded by dense fibrous connective tissue, CT, AV bundle (A-I) is seen being impinged upon and invaded by the fibro-calcareous mass (100 \times mag)

calcereous mass into two parts. Each mass measured approximately 1.5 mm. in diameter and 6 mm. in length. Near the ends of the mass it became smaller and narrower and finally disappeared. The mass ran parallel to the base of the aortic leaflet of the mitral valve (figure 2). The mass was largely on the left side of the septum, it impinged upon the A-V bundle near the center and at some places was seen to invade the bundle substance. Small portions of calcified material were seen scattered around the main mass. The A-V bundle and its branches were apparently normal in cellular structure throughout. There were a few lymphocytes in and around the mass.

The muscular septum was quite hypertrophied as were the individual muscle cells. There were no endothelial changes of note and conduction system was apparently normal in cellular structure. The aortic valves showed evidences of slight calcification in their bases, but were otherwise competent. A number of small arteries around the calcified mass showed definite sclerotic changes but none were completely obliterated. The coronary arteries were definitely sclerosed. The photograph of the heart and photomicrographs further add to this description.

We wish to express our appreciation to Dr. John S. Lantford, Director of the Department of Pathology, Toussaint Infirmary, New Orleans, who performed the autopsy.

EDITORIAL

CUSHING'S SYNDROME AND TUMORS OF THE ADRENAL CORTEX

IN 1932, Cushing¹ published an account of the syndrome which now goes by his name and which he called pituitary basophilism. As is well known, he was able to collect a group of cases associated with basophilic tumors of the hypophysis, all of which showed some or many of the following characteristics: adiposity of the face, neck, and trunk, the extremities not being affected, vascular hypertension, hirsuties, particularly of the face and trunk in females, impotence or amenorrhea, cyanosis and edema of the extremities, a tendency to polycythemia, with a florid or plethoric complexion, dryness of the skin, often with acne, and particularly with purplish lineae atrophicae, osteoporosis, glycosuria or albuminuria, and variable backache, weakness, and fatigability. Other cases were soon reported, but it became evident that such a syndrome might also occur in the absence of a pituitary tumor, associated with other endocrine lesions particularly of the suprarenal cortex and thymus^{2,3}. Pituitary basophilism, therefore, or a syndrome which cannot be distinguished from it, although frequently accompanied by a pituitary growth, is not invariably so related. Examination of a large number of pituitary glands by Costello,⁴ with serial sections, in cases where no endocrine disturbance was obvious clinically, also indicated that such tumors were to be found in the absence of the symptoms which have been described.

Studies recently reported by Crooke⁵ may have fundamental importance in throwing light upon this problem. He has discovered that a hyaline change is present in the basophilic elements of the anterior pituitary, often with cellular distortion, and with a diminution in the number of basophilic granules present, in cases of pituitary basophilism. The lesion is not found in the basophilic adenomata when present, but only in the proper glandular tissue. This change was found not only in cases of Cushing's syndrome with basophilic adenoma of the pituitary, but also in similar clinical disorders in which neoplasms of the thymus, or growths or hyperplasia of the adrenal cortex, were the conspicuous lesion, and in which a basophilic pituitary

adenoma was not found after most careful search. All of these cases suffered from hypertension, as did those described by Cushing. Crooke believes this hyaline change in the basophiles is an expression of altered physiological activity rather than a degenerative change in the ordinary sense. He has also made interesting observations on the pituitary in Addison's disease, where extreme reduction in the number of basophiles and the presence of abnormal basophilic transitional cells are to be found. Nicholson⁶ has reported recently a difference in the histologic picture in pituitary glands from patients with Addison's disease due to cortical atrophy and those due to tuberculosis. Only in the first group was he able to show reduction in the number of basophiles and the appearance of abnormal basophilic cells. Crooke suggests that this reduction in these elements is associated with the cause of the hypotension and perhaps of the hypoglycemia which are found. Since cortical hormone therapy in Addison's disease does not seem to influence this pituitary lesion, a plausible reason is afforded for the slight effect which it also has on the clinical course of the hypotension.

Other relationships of the adrenal cortex are indicated, however, by certain cases of cortical tumor which instead of being associated with Cushing's syndrome exhibit the even more striking clinical phenomena of stimulation or reversal of sex. In this they seem to show a sharp difference from the first named condition, in which the characteristic sex changes are those of inhibition or depression rather than of virilism. There is, however, considerable uncertainty as to just how clear a distinction may be drawn between the two conditions. If a hormonal principle, elaborated by the tumor cells, is responsible for the sex changes as seems altogether likely, it would appear to be more closely related to the gonads than to the pituitary. Removal of the tumor, in a number of brilliant instances, has resulted in practical cure of the patient, with disappearance of the abnormal sex phenomena.⁷ It seems probable that the salt and water hormone of the adrenal cortex, which is to a certain degree effective in Addison's disease, has nothing to do with this sex reversal or sex stimulation, at least not in any clear and direct way. This is, of course remarkable, since the methods of extracting this material, by means of lipid solvents, are precisely those which have been found so effective in the isolation of the gonadal hormones. Hartman has, indeed, reported a separate lactogenic principle from the adrenal cortex.⁸ The evidence available, therefore does seem to suggest that more than one hormonal principle may be present in the adrenal cortex.

The closely related embryological origin of adrenal cortex and gonads, within the genital ridge, and the occurrence of the "X" layer between reticularis and medulla in embryonic life, are circumstances undoubtedly of great significance. The presence of this layer is believed to be responsible

for the relatively great size of the fetal adrenal. At one period of gestation it equals the kidney in size, and at birth it is still one-third the size of the latter organ.⁹

Much of the accessory cortical tissue, particularly that in association with the reproductive organs, may well be a part of this tissue, a glandular entity, quite distinct in function from the rest of the cortex. Its involution normally begins soon after birth and is nearly complete at the end of the first year. A thin juxta-medullary zone of pigmented cells is said to persist in the adult and may be a remnant of this involuted tissue. Hypertrophy or persistence of portions of it which have not undergone involution, according to one theory, may be responsible for the adreno-genital syndrome associated with tumors of the cortex. Broster and Vines¹⁰ report the occurrence of bright red granules, upon staining with Ponceau-Fuchsin, in the cytoplasm of adrenal cells of the reticular layer in such tumors, and find that they are also normally present in the "X" layer of embryonic life. If confirmed, such a finding would point to the undue persistence of cells from this layer into later life as one causal factor in the production of these conditions of sex reversal and stimulation. Others, however, have not been so fortunate in the demonstration of this staining reaction, and its regular occurrence in these cases is as yet not certain.

This recent evidence for the occurrence of two types of adrenal cortical tissue, quite different in their physiological significance, constitutes a new and probably an important advance in our progress toward a final solution of the problem of adrenal function.

REVIEWS

Textbook of Psychiatry By ARTHUR P. NOYES M.D. Second Edition 329 pages, 15 X 22 cm Macmillan Co., New York 1936 Price, \$2.50

Dr. Noyes offers a revised edition of his popular textbook which found such wide acceptance when first issued in 1927.

It is primarily intended for nurses, but presents one of the best simple understandable expositions of mental mechanisms and psychiatric reaction types that we know. It is in no sense exhaustive. It is designed to give the nurse some idea of what mental disease is and a brief picture of the symptoms occurring in various types of mental reaction.

The first nine chapters are devoted to dynamics of normal and abnormal behavior and to explanation of accepted American theories as to the causes underlying emotional disorders. Most of the rest of the book devotes itself to description of clinical pictures as typically found. At the end of each clinical picture there is a short section called "Nursing Management" which gives practical suggestions as to things which the nurse can actually do to protect and help her patient. At the end of the book there is a good chapter called "Psychiatric Nursing" and a brief survey of the author's views on psychoanalysis and mental hygiene. The book ends with a fairly complete glossary of the commoner psychiatric terms.

The whole volume is clear, conservative and should be very useful to medical students or to busy general practitioners who want some concrete suggestions as to how to handle their patients. Nowhere are there any attempts to explain psychotherapy, since this of course does not fall within the nurse's province, but for everything else we can recommend the book.

H. M.

The Parathyroids in Health and in Disease By DAVID H. SHILLING B.Sc., M.D. 335 pages, 17 X 25 cm, illustrated C. V. Mosby Company, St. Louis 1935 Price, \$5.00

This excellent book should prove quite valuable to special workers as well as to teachers and to those physicians and students who arrange for themselves the time to read authoritative monographs on special subjects.

The author is an acknowledged authority in the field of research on the parathyroids both experimental and clinical. His style is clear and concise. He has arranged the subject matter of the book into ten chapters dealing with the history, the anatomy, the pathology, the physiology of the parathyroids, the parathyroid hormone, tetany and hypoparathyroidism, hyperparathyroidism and osteitis fibrosa, the relation of the parathyroids to the other glands of internal secretion, the relation of the parathyroids to vitamin D, and the use and misuse of parathyroid hormone and of parathyroidectomy.

Numerous references in the text are made to the very full bibliography at the end of each chapter. It would seem to the reviewer that the world literature on the subject has been completely covered and listed.

The general excellence of the book is enhanced by the attractive format of the volume, of convenient size, excellent paper and print with many side headings in heavy black type.

T. P. S.

Cardiac Output and Arterial Hypertension By SIDNEY A. GLADSTONE, M.D. 56 pages, 16 × 23.5 cm 1935 Price, \$1.00

This small volume contains four papers, the first two dealing with the foreign gas methods of determining cardiac output, the third with the cardiac output in hypertension and the fourth presents an hypothesis concerning the mechanism of renal hypertension.

In the first two papers the author offers criticisms of the existing methods of determining cardiac output and presents his own modification of the acetylene method. In the third paper using his modification of the acetylene procedure, he presents evidence that the increased work of the heart in cases of essential hypertension is due to increased peripheral resistance and not to an increased cardiac output. The fourth paper is speculative in nature, and presents no experimental work of the author in support of his conclusions.

W. S. L., JR.

Roentgenographic Technique: A Manual for Physicians, Students and Technicians By DARMON ARTHEM RHINGGART, A.M., M.D., F.A.C.R., Professor of Roentgenology and Applied Anatomy, School of Medicine, University of Arkansas, Roentgenologist to St. Vincent's Infirmary, Baptist State Hospital, Missouri Pacific Hospital and the Arkansas Children's Hospital, Little Rock, Arkansas. Second Edition. 431 pages, 16 × 24 cm, 183 engravings. Lea and Febiger, Philadelphia. 1936. Price, \$5.50.

This is a thorough and successful attempt to present for physicians, students and technicians a text of time-tested roentgenographic technique as well as modern advances. Salient features of the volume are simplicity and comprehensiveness. The principles are presented in an orderly and logical fashion with emphasis on seemingly insignificant details of roentgenographic technique which make for thorough roentgenographic work. The sections on electricity and roentgen-ray machines and their accessories appear to be adequate to furnish the ground work for intelligent understanding of the principles.

A series of experiments is incorporated which should furnish invaluable information concerning operating characteristics of roentgen-ray machines, the laws of roentgen-ray exposure, and patient-tube-film relationship, so that the best films will be obtained. A technique based on thickness and radiographic density is advocated, a sound and universal method for obtaining consistently good roentgenograms. Sections on the radiographic peculiarities of the various parts of the body are included. The many methods of examining the various parts are mentioned, the best being more fully considered. The book should prove useful to any physician who desires a comprehensive knowledge of radiographic technique.

H. J. W.

Evaluation of Symptoms By OLIVER T. OSBORNE, M.D. 163 pages, 14 × 21 cm. Yale University Press, New Haven, Connecticut. 1935. Price \$3.50.

The author has written a small book in which he summarizes in seven chapters points which his long experience has shown him to be of particular value to the practicing physician. He discusses history taking, examination, principles of therapy, certain specific diseases and then takes up symptoms separately in alphabetic order. There is a great deal of information in small compass.

M. C. P.

COLLEGE NEWS NOTES

GIFTS TO THE COLLEGE LIBRARY

Acknowledgment is made of the receipt of the following gifts to the College Library of publications by members

- Dr Wm W Cadbury (Fellow) Moorestown N J on leave of absence
Canton China—1 autographed book, 'At the Point of a Lancet',
Dr Logan Clendinning (Fellow), Kansas City Mo—1 book 'The Balanced Diet',
Dr R Manning Clarke (Fellow) Los Angeles Calif—1 reprint,
Dr Albert Sorland (Fellow) Los Angeles Calif—2 reprints
Dr William E Costelow (Fellow), Los Angeles Calif—1 reprint,
Dr Isidore Lattman (Associate), Washington D C—3 reprints
Dr G Philip Gibbfield (Fellow), Boston Mass—18 reprints
Dr Samuel J McClendon (Fellow) San Diego Calif—2 reprints,
Dr Oliver I Osborne (Fellow) New Haven, Conn—1 reprint
Dr L B Caruthers (Associate), Miraj India—2 reprints,
Dr William C Cooke (Associate) San Diego, Calif—2 reprints,
Dr Warren W Quillian (Associate) Coral Gables, Fla—4 reprints,
Dr Joseph B Wolfe (Associate) Philadelphia Pa—2 reprints

THE WASHINGTON SCHOOL OF PSYCHIATRY

Early in 1933, the Training Committee of The Washington-Baltimore Psychoanalytic Society began a formal schedule of didactic lectures and seminars in keeping with the tradition of branch societies of The International Psychoanalytical Association. These training courses have been continued regularly from the beginning. The Committee incorporated the William Alanson White Psychoanalytic Foundation, and is now in view a psychoanalytic institute similar to that maintained in other training centers. However, experience of teaching and training dictated the need for graduate work in every field of interest to the psychiatrist. This led to plans for a school that would represent most truly American psychiatry and which would be limited in its scope. The outgrowth has been the incorporation of The Washington School of Psychiatry, with Dr White as its Honorary President. Among its officers in addition to Dr White, who is a Fellow of the American College of Physicians, are the following

- Dr Harry Stack Sullivan, President and Chairman of the Faculty
Dr Lucile Dooley, Vice-President
Dr Ross McClure Chapman (Fellow), Vice-President and Provost
Dr William K Ryan, Treasurer
Dr Ernest E Hadley (Associate), Secretary and Executive Director
Dr Joseph L Gilbert (Fellow), Registrar

STATE MEETING—ILLINOIS MEMBERS

The second annual meeting of the members of the American College of Physicians of the State of Illinois, outside of Chicago, was held September 24, 1936, at Peoria. The meeting was called by Dr Samuel E Munson, of Springfield, Governor for Southern Illinois, and the invitations were sent by Dr George Parker, of Peoria.

The meeting was held at the Creve Couer Club, and opened at four o'clock with the following guest speakers

- Dr Allen K Krause (Fellow) Baltimore, Md—"Future Possibilities of the Diagnosis of Tuberculosis",
 Dr Horace W Soper (Fellow), St Louis Mo—"Clinical Significance of Milk and Cholesterol in the Dietary of Man",
 Dr Frank Smithies (Master), Chicago, Ill—"Certain Ulcerative Lesions of the Bowel, Their Recognition and Management"

Dinner was served at six-thirty, after which a short report was made by Dr Samuel E Munson, Governor for Southern Illinois, who spoke in regard to the work of the committee that had been appointed about two years ago to act in connection with the Section on the Practice of Medicine of the American Medical Association to form an American Board for the purpose of establishing rules for the qualification of candidates and conducting examinations. This was accomplished in June of this year, with such rules and regulations as will govern its requirements for certification of those desiring to become internists. He also spoke of the officers of the College having acquired a suitable and permanent home for the College in Philadelphia. In addition to other requirements available, conference rooms may be used by members of the College as headquarters when in Philadelphia.

Dr Munson stated that inasmuch as the meeting at Springfield last year so unanimously met with approval, it was decided to accept the invitation of the Peoria Fellows and meet with them this year. It was agreed that no mistake was made in accepting this invitation, as we had ample proof of their cordiality and hospitality as good fellows upon this occasion.

When the call for this meeting reached the members through Dr George Parker, and the names of those who were to address the meeting were read, a thrill of pleasure and appreciation was felt that these distinguished Fellows were to be our guests and speakers. Not only were we honored by their presence as guests, but as clinicians and writers whose names are well known as authorities in their respective fields of medicine.

One of our guests whose name for many years has been synonymous with the most advanced thought in the diagnosis and treatment of tuberculosis, Editor of the *American Review of Tuberculosis*, was Dr Allen K Krause, of Baltimore.

Another whose name has been no less widely known as a teacher and author in the field of diseases of digestion was Dr Horace W Soper, of the Soper-Mills Clinic, St Louis.

Our third speaker, Secretary-General of the College from 1922 to 1926, and later its President, and the only one in Illinois who has been honored by being made a Master of the College, now Editor of the *American Journal of Digestive Diseases and Nutrition*, was Dr Frank Smithies, of Chicago.

In their letters of acceptance, each of these men expressed the appreciation and honor they felt in receiving an invitation to address the Fellows of the College from Illinois.

The following members of the College were present: Thomas A Starkey, of Beardstown, Gerald M Cline, Henry W Grote, Edgar M Stevenson, of Bloomington, D O N Lindberg, Perry J Mehuck, of Decatur, James C Redington, of Galesburg, Albert H Dollear, Warner H Newcomb, of Jacksonville, Orville Barbour, Harry A Durkin, Fred M Meixner, George Parker, Maxim Pollak, John R Vonachen, of Peoria, Warren F Pearce, Hildegard C Germann Sinnock, Harold Swanberg, of Quincy, Major Eugen G Remartz, of Chanute Field, Rantoul, Samuel E Munson, Thomas D Masters, Emmet F Pearson, George B Stericker, of Springfield, Villairs T Austin, Charles H Drenehahn, of Urbana.

There were also present about fifteen guests, invited by the Peoria Fellows, and Dr R L Green, of Peoria, President of the Illinois State Medical Society.

SPECIAL MEETING, BOARD OF REGENTS

A meeting of the Board of Regents of the American College of Physicians has been called by the President, Dr Ernest B Bradley at the College Headquarters in Philadelphia on December 13, 1936. Various committees of the College will meet December 12, as will also the American Board of Internal Medicine. About two hundred and fifty candidates for Associateship or Fellowship are to be considered and much other important College business will be transacted. The Committee on Constitution and By-Laws will present suggested amendments to the by-laws governing the admission of future candidates to Fellowship. The Committee on Future Policy for the Development of Internal Medicine may also present to the Regents recommendations for additional activities of the College in the future.

The New York Post-Graduate Medical School and Hospital conducted a Symposium on Dysentery September 26 1936. Among those presenting papers were Dr George W McCoy (Fellow), Director of the National Institute of Health Washington, D C, "Relationship of the Problem of Dysentery to the U S Public Health Service", Dr Ward J MacNeal (Fellow) Professor of Pathology and Bacteriology, New York Post-Graduate Medical School. "Bacteriophages in the Treatment of Intestinal Disease". Dr Z Bercovitz (Associate) Instructor in Medicine New York Post-Graduate Medical School, "Methods for Differential Diagnosis in Dysentery". Dr Walter G Lough (Fellow) Executive Officer, Department of Medicine, New York Post-Graduate Medical School acted as Chairman of that part of the program dealing with "Dysentery and the Clinician".

Dr D O N Lindberg (Fellow) Decatur, Ill, has been elected President of the Mississippi Valley Sanatorium Association.

Dr G Harlan Wells (Fellow) Philadelphia was elected President of the Homeopathic Medical Society of Pennsylvania on September 23, 1936. Dr E Roland Snader (Fellow), Philadelphia, was elected a trustee and Dr E W Stitzel (Fellow), Altoona, was elected censor.

Dr Frank S Horvath (Associate), Washington, D C, has been appointed Associate Professor of Clinical Medicine at Georgetown University School of Medicine.

Dr W D Weis (Fellow), County Health Commissioner for Lake County, Ind brought more forcibly to the residents of that County the matter of health and sanitation by having a Health and Sanitation Exhibit at the Lake County Fair during the past autumn. Exhibits and demonstrations were arranged under Dr Weis' direction by the Northwest Indiana Dental Society, the Lake County Tuberculosis Sanatorium, the Lake County Tuberculosis Association, the Weights and Measures Division of the Indiana Department of Public Health, the League for the Hard of Hearing, the Health Department of the City of Hammond, the Milk and Dairy Division of the Indiana Department of Public Health, the Lake County Safety Council, the Lake County Health Department and other agencies. Resort was made to motion pictures, charts, maps and various other means by which the interest of the citizens would be aroused and a proper impression of the importance of health measures carried to the homes throughout the County.

The Mississippi Valley Medical Society, being the Tri-State Post Graduate Assembly of Illinois, Missouri and Iowa, held its second annual meeting at Burlington Iowa, September 30 to October 2. Among the guest speakers was Dr Ralph Kinsella.

(Fellow), St Louis, Mo, representing Internal Medicine Dr Willard O Thompson (Fellow), Chicago, Ill, and Dr Leon Unger (Associate), Chicago, Ill, presented scientific exhibits on "Glands of Internal Secretion" and "Allergy," respectively. Among the clinical lecturers were Dr James G Carr (Fellow), Chicago, Ill, Dr Charles A Elliott (Fellow), Chicago, Ill, Dr F H Lamb (Associate), Davenport, Iowa, Dr Frank P McNamara (Fellow), Dubuque, Iowa, Dr Joseph L Miller (Fellow), Chicago, Ill, Dr Warren Pearce (Fellow), Quincy, Ill, Dr John H Peck (Fellow), Des Moines, Iowa, Dr J C Redington (Associate), Galesburg, Ill, Dr Howard Rusk (Fellow), St Louis, Mo, Dr Leon Unger (Associate), Chicago, Ill, and Dr Italo F Volini (Fellow), Chicago, Ill.

Among the officers of the Society were Dr D G Stine (Fellow), Columbia, Mo, First Vice-President, Dr J I Marker (Fellow), Davenport, Iowa, Third Vice-President, and Dr Harold Swanberg (Fellow), Quincy, Ill, Secretary-Treasurer Dr G M Cline (Fellow), Bloomington, Ill, Dr Harold Swanberg (Fellow), Quincy, Ill, and Dr E S Smith (Fellow), Kirksville, Mo, are members of the Board of Directors.

Dr Maximilian J Hubeny (Fellow), Chicago, has been made chief of the X-Ray Department of Cook County Hospital.

Dr George B Eusterman (Fellow), Rochester, Minn, Dr Alan Brown (Fellow), Toronto, Ont, and Dr Elliott P Joslin (Fellow), Boston, Mass, were among the guest speakers on the program of the Omaha Mid-West Clinical Society, held at Omaha, October 26 to 30.

Dr James J McGuire (Fellow), Trenton, has been elected Secretary of the New Jersey State Board of Medical Examiners.

Recent promotions on the Faculty of the College of Physicians and Surgeons of Columbia University include the following:

Dr J Burns Amberson, Jr (Fellow), Professor of Clinical Medicine
 Dr Robert L Levy (Fellow), Professor of Clinical Medicine
 Dr Alvan L Barach (Fellow), Assistant Professor of Clinical Medicine
 Dr Charles A McKendree (Fellow), Clinical Professor of Neurology

Dr Clarence M Grigsby (Fellow and former Governor for Texas), Professor of Clinical Medicine at Baylor University College of Medicine, Dallas, was guest of honor at a recent dinner celebrating his completion of twenty-five years as a member of the faculty of that institution.

Dr Ramon M Suarez (Fellow and Governor for Puerto Rico) addressed the first scientific meeting of the Puerto Rico chapter of the Pan American Medical Association in San Juan recently, on "The Study of the Bone Marrow in Chronic Schistosomiasis Mansonii."

Sir Frederick Banting (Fellow) and Dr Charles H Best, both of the University of Toronto Faculty of Medicine, and Dr James B Collip (Fellow), McGill University Faculty of Medicine, Montreal, were the recipients of the Frederick Newton Gisborne Starr Medal awarded at the last meeting of the Canadian Medical Association "for preeminent services to the cause of medicine in Canada." The Starr Medal was established in 1935 by the widow of the late Dr Starr, who for several years was the General Secretary of the Association, and President in 1927.

Among the guest speakers at the annual meeting of the Indiana State Medical Association at South Bend, October 6 to 8, were the following Fellows of the College

Dr Byrl R Kirklin, Rochester, Minn
Dr Russell L Cecil, New York City
Dr Francis E Senear, Chicago, Ill
Dr Elmer L Sevringhaus, Madison, Wis
Dr John A Ioomer, Cleveland, Ohio

Dr Hugo A Freund (Fellow), Detroit, President of the Children's Fund of Michigan, presented a symposium on "What Constitutes a Complete Health Service for the Community?" at a conference between the University of Michigan and the Fund, at Marquette, recently Dr Arthur C Curtis (Fellow), Ann Arbor, delivered an address on "Etiology and Management of Chronic Arthritis"

The following Fellows of the American College of Physicians addressed the Fourteenth Annual Conference of the Kansas City Southwest Clinical Society at Kansas City, October 4 to 8

Dr Milton A Bridges, New York City
Dr Joseph A Capps, Chicago, Ill
Dr J Arthur Myers, Minneapolis, Minn

Dr Morris Maslon (Fellow), Glens Falls, N Y, was a guest of honor at a testimonial dinner at the Fort William Henry Hotel, Lake George, recently, celebrating his twenty-fifth anniversary as head of the Warren County Laboratory

Dr Coy C Carpenter (Fellow), who has been acting dean of Wake Forest College of Medicine, Wake Forest, N C, has now been elected dean to succeed Dr Thurman D Kitchin (Fellow), who was made president of the College in 1930

Dr Edward S King (Associate), Professor of Physiologic Chemistry and Bacteriology, is on leave of absence, spending the present term at Harvard University Medical School, Boston

The first "Harlow Brooks Memorial Navajo Clinical Conference" was held August 31 to September 1 at Ganado, Ariz Among the speakers was Dr Milo K Tedstrom (Fellow) of Santa Ana, Calif The conference will be held annually and is named in honor of the late Dr Harlow Brooks (Fellow), New York City, who was interested in the work of the Sage Memorial Hospital at Ganado, which is in the heart of the Navajo reservation Dr Brooks was an authority on Indian practices and customs

The Iowa State Medical Society has been offering graduate courses in various Iowa cities during the present autumn Dr Arthur U Desjardins (Fellow), Rochester, Minn, gave a lecture on "Evaluation of Radiologic Diagnosis and Treatment of Cancer", Dr Samuel A Levine (Fellow), Boston, "Modern Cardiac Therapy", Dr William S Middleton (Fellow), Madison, Wis, "The Barbiturates in the Treatment of Disease", Dr Paul A O'Leary (Fellow), Rochester, Minn, "Treatment of Syphilis", Dr Philip S Hensch (Fellow), Rochester, Minn, "Diagnosis and Treatment of Arthritis", Dr Maurice C Howard (Fellow), Omaha,

Nebr, "Diagnosis and Treatment of the Anemias", Dr Byrl R Kirklin (Fellow), Rochester, Minn, "Roentgenologic Diagnosis", and Dr Russell M Wilder (Fellow), Rochester, Minn, "Modern Treatment of Diabetes"

Dr John Harvey (Fellow), Lexington, Ky, delivered the annual oration in medicine of the Kentucky State Medical Association at Paducah on October 6, his subject being "Our Duty to the Art and Science of Medicine"

Dr George Herrmann (Fellow), Galveston, Tex, addressed the seventy-first annual meeting of the Michigan State Medical Society, September 21 to 24, on "Further Studies of the Mechanism of Action and of the Relative Effectiveness of the Newer Diuretics"

The Ohio State Medical Association held its ninetieth annual meeting in Cleveland, October 7 to 9, under the presidency of Dr Ralph R Hendershott (Associate), Tiffin, Ohio

Dr Samuel A Levine (Fellow), Boston, assistant professor of medicine, Harvard University Medical School, delivered a lecture on "Diseases of the Heart and Allied Pathologic Conditions" in connection with the graduate lectures sponsored by the Lima and Allen County (Ohio) Academy of Medicine during September

The Medical Society of Milwaukee County, Wisconsin, sponsored a course of graduate lectures on syphilis given at Marquette University School of Medicine, Milwaukee, recently. Among the lecturers and their subjects were

Dr Udo J Wile (Fellow), Ann Arbor, Mich, 'Bone, Joint and Visceral Syphilis", Dr James E Paulin (Fellow), Atlanta, Ga, "Public Health Aspects of Syphilis", and Dr Paul A O'Leary (Fellow), Rochester, Minn, "Treatment of Syphilis"

Col Henry C Pillsbury (Fellow), Medical Corps, U S Army, has been assigned to duty as chief health officer of the Panama Canal Zone

Dr Frank H Krusen (Associate), Rochester, Minn, and Dr William J Egan (Fellow), Milwaukee, Wis, have been elected vice-presidents of the American Congress of Physical Therapy for the coming year

Dr Ernest B Bradley (Fellow and President) addressed the Jefferson and Fayette County Medical Societies at Louisville, Ky, September 21, on "A Medical Glance at the Past Thirty Years"

Dr George W McCoy (Fellow), Director of the National Institute of Health, Washington, D C, was one of the speakers on the occasion of the dedication of the new public health laboratory of the New York City Department of Health, named in honor of Dr William Hallock Park, founder and director emeritus of the laboratory

Dr William S McCann (Fellow), Rochester, N Y, and Dr Elliott P Joslin (Fellow), Boston Mass, were guest speakers at the eighty-sixth annual meeting of the Medical Society of the State of Pennsylvania, held in Pittsburgh October 5 to 8

Dr Kenneth M Lynch (Fellow) and Dr Joseph H Cannon (Fellow), both of Charleston, S C, and Dr James E Paullin (Fellow), Atlanta, Ga, delivered lectures on diseases of the kidney at the second annual clinical assembly presented by the Anderson County (South Carolina) Medical Society, September 8 to 10

Dr Edgar A Hines (Fellow), Seneca S C, was president of the assembly

Dr John A Kolmer (Fellow), Philadelphia, and Dr Josephine B Neal (Fellow), New York City conducted a panel discussion on poliomyelitis in connection with the fourth annual fall clinical session of the Maine Medical Association, held at Waterville, Maine, October 15 to 16

Dr Paul Dudley White (Fellow) assistant professor of medicine, Harvard Medical School, delivered the principal address on the occasion of Ether Day at the Massachusetts General Hospital, October 16

The New York Academy of Medicine presented its ninth annual graduate fortnight October 19 to 31, on "Trauma Occupational Diseases and Hazards" Among the speakers and their subjects were

Major Samuel A White (Fellow), Medical Corps, U S Army "Medical Aspects of Chemical Warfare", Dr Elliott P Joslin (Fellow), Boston, "Relation of Trauma to Diabetes", and Dr J Burns Amberson, Jr (Fellow), New York City, "Pulmonary Disease"

The late Dr James M Anders (Master), Philadelphia, who died August 29, provided in his will after the death of his widow \$50,000 for the establishment of the James M Anders Foundation in the Graduate School of Medicine of the University of Pennsylvania, \$2,500 to the Philadelphia County Medical Society to defray the expenses of the annual "Public Health Day" in the public schools, \$2,000 for the endowment fund of the Society's library, and further provided that the library committee of the Philadelphia County Medical Society may select such books from his library as they choose

Dr Julius H Hess (Fellow), Chicago, and Dr John A Toomey (Fellow), Cleveland, will be guest speakers at the fourth annual meeting in Atlanta of the Georgia Pediatric Society, December 10

Dr Wyndham B Blanton (Fellow), professor of the history of medicine, Medical College of Virginia, has been appointed one of the editors of the "Annals of Medical History"

The seventh annual fall clinical conference of the Oklahoma City Clinical Society was held October 26 to 29 Among the speakers and their titles were the following

Dr Wilburt C Davison (Fellow), Dean of the School of Medicine and Professor of Pediatrics, Duke University, Durham, N C—Pediatrics,
 Dr Charles L Brown (Fellow), Professor of Medicine and Head of the Department of Medicine, Temple University School of Medicine, Philadelphia—Internal Medicine,

Dr F E Senear (Fellow), Professor and Head of the Department of Dermatology, University of Illinois College of Medicine, Chicago—Dermatology,
Dr Hans Lissner (Fellow), Clinical Professor of Medicine, University of California Medical School, Berkeley-San Francisco—Endocrinology

Dr F O Mahony (Fellow), El Dorado, Ark, has been appointed vice-president of the State Board of Health

Dr Paul Brindley (Fellow), Galveston, and Dr May Owen (Fellow), Fort Worth, have been elected president and vice-president respectively of the Texas State Pathological Society

Dr Alex F Robertson, Jr (Fellow), Staunton, Va, has been elected secretary of the Augusta County (Virginia) Medical Society

Honoring the sixty-seventh birthday of Dr Francis M Pottenger (Fellow and ex-President), a large number of patients and former patients joined members of Dr Pottenger's family and the Staff of the Sanatorium in an informal reception given for him on Sunday afternoon, September 27, in the beautiful gardens of the Pottenger Sanatorium at Monrovia, Calif. There were about two hundred guests present, among whom were patients who left the Sanatorium as far back as 1905

Dr Pottenger received many beautiful gifts from associates and patients, and congratulatory telegrams from patients and friends unable to attend. A buffet supper was served in the gardens

Major James Stevens Simmons (Fellow), Medical Corps, U S Army, who in 1934 organized the Army Medical Research Board, Ancon, Canal Zone, and who during the past two years has been engaged in an investigation of malaria and its anopheline vectors in Panama, has been transferred for duty as Assistant to the Corps Area Surgeon, Headquarters First Corps Area, Army Base, Boston, Mass

Dr Chester North Frazier (Fellow), Professor of Dermatology and Syphilology, Peiping Union Medical College, Peiping, China, is on furlough and is engaged in studying biostatistics in the School of Hygiene and Public Health of the Johns Hopkins University, Baltimore

Dr Paul P McCain (Fellow), Medical Director of the North Carolina Sanatorium for the Treatment of Tuberculosis, has been awarded the degree of LL D by the University of North Carolina

Dr Perry J Melnick (Associate), Decatur, Ill, received the degree of Doctor of Philosophy in Pathology from the University of Illinois College of Medicine last June

Dr Allen K Krause (Fellow), Director of the Desert Sanatorium, Tucson, Ariz, is on leave of absence and is now in Baltimore, Md, where he was formerly Associate Professor of Medicine on the faculty of Johns Hopkins University. Dr Krause still retains the title of Lecturer in Medicine at Johns Hopkins University School of Medicine, and is a "Fellow by Courtesy in Epidemiology" in the Johns Hopkins School of Hygiene. He is Editor of the "American Review of Tuberculosis," and during the coming year will devote his time to study and writing

OBITUARIES

DR WILLIAM H MAYER

In the death of Dr William H Mayer (Fellow) on August 22, 1936, from septic pneumonia, organized medicine lost one of its most loyal supporters, one who in spite of almost unsupportable physical handicap had been unsparing of time and energy in his devotion to the affairs of his county and state societies and of the American Medical Association

Dr Mayer was born in Pittsburgh, Pa, October 30, 1887, the son of William L and Anna Bickman Mayer

He received his preliminary education in Pittsburgh Central High School, and after graduating from the University of Pennsylvania Medical School in 1912, served his internship in Mercy Hospital, Pittsburgh. Entering into practice he devoted himself to the field of neurology and psychiatry. Dr Mayer was Neurologist to Allegheny General Hospital and Passavant Hospital, Associate Psychiatrist to St Francis Hospital, Assistant Professor of Neurology in the School of Medicine of the University of Pittsburgh. In addition to membership in the County and State societies he was a Fellow of the American Medical Association, the Pittsburgh Academy of Medicine and the American College of Physicians. He was a member, also, of the American Psychiatric Association and of the Association for Research in Mental and Nervous Diseases.

Dr Mayer served as secretary of the Allegheny County Medical Society from 1917 to 1925, in which year he became President-Elect of the Medical Society of the State of Pennsylvania.

He also served his county society, as a member of the Board of Directors, chairman of the Finance Committee, and as elected delegate to the State Society. In 1931 he was installed as President of the Medical Society of the State of Pennsylvania. Consecutively, since 1921 he was chosen to succeed himself as delegate from his State Society to the House of Delegates of the American Medical Association.

Dr Mayer was twice married, his first wife was Miss Emma J Glass of London, Ontario, who died several years ago. He later married Miss Virginia Diehl Sutton of Pittsburgh, who with their baby daughter, Ann Virginia, born February 29, 1936, survives him.

E BOSWORTH MCCREADY, M D, F A C P,
Governor for Western Pennsylvania

DR HOWARD E MARCHBANKS

Dr Howard E Marchbanks (Fellow), of Pittsburg, Kansas, died August 7, 1936, of coronary occlusion.

Dr Marchbanks was born in Scammon, Kansas, July 18, 1888. He graduated from Cherokee High School, entered the University of Kansas

and received his A B He then entered the University of Kansas Medical School and graduated in 1916 He served his internship at the Bell Memorial Hospital in Kansas City, Kansas

He was a member of the Phi Beta Pi Medical Fraternity During the World War he served as First Lieutenant in the Medical Corps attached to the 218th Engineers He received his discharge from the service February 4, 1919

In 1919 Dr Marchbanks took postgraduate work under Dr Richard Cabot in the Harvard Medical School at Boston He was a member of the American Medical Association, The Kansas Medical Society, The Southeast Kansas Medical Society, The Jackson County (Missouri) Medical Society He was one of the associate editors of the Journal of the Kansas Medical Society In 1931 Dr Marchbanks was made a Fellow of the American College of Physicians

THOMAS T HOLT, M D , F A C P ,
Governor for Kansas

THE MANNER IN WHICH FOOD CONTROLS THE BULK OF THE FECES

By RAY D. WILLIAMS, M.S., and W. H. OLMSFED, M.D.,
St. Louis, Missouri

EVERYONE is fully aware that the causes of constipation are numerous. It is often very difficult to determine the relative importance of each factor. There are many normal people who, although consuming very concentrated, highly purified, non residue diets, are nevertheless rarely constipated. Others there are who in spite of using all possible dietary aids are not able to have a daily evacuation of the bowels. So there is considerable doubt in our minds as to whether food is the main factor in determining the regularity of stool evacuation. Furthermore, there is abundant room for argument as to whether or not a daily evacuation is necessary for the maintenance of sound health.

One need not be concerned with the causes or clinical import of constipation to be able to prove that in a given normal individual one can markedly affect the stool volume by dietary means.

In this paper we wish to present the experimental results accumulated from time to time over the past several years by using as experimental subjects medical students who trained themselves to a regular time for stool evacuation. It is our conviction that results in this field are much more convincing and applicable if the human subject is used as the experimental animal. With these normal individuals we propose to show the effects of food on the volume of the stool. We shall then explain partially at least the results found.

EFFECTS OF DIGESTIBLE PROTEIN, FAT AND CARBOHYDRATE

Both clinicians and physiologists agree that the indigestible carbohydrates of foods have a greater effect on stool volume than the digestible and absorbable protein, fat and carbohydrate. Nevertheless, one can easily

* Presented at the Detroit meeting of the American College of Physicians, March 2, 1936.
From the Department of Medicine, Washington University School of Medicine, and the Barnes Hospital, St. Louis, Missouri.

show the effect of carbohydrate even in the case of non residue diets on the volume of the stool. In table 1 are recorded the results of an experiment carried out in 1929¹ on three students. It can be seen that when there was a predominance of carbohydrate in the diet, the stool volumes exceeded those found in the periods of either high protein or high fat feeding. When much protein was fed, the small stool volume is very evident. Although all three subjects' stool volumes increased on high carbohydrate diets, there are differences in the individual responses. This illustrates the difference found among normal individuals.

The explanation of the different effects of protein, fat and carbohydrate on the stool volume lies in the fact that even in case of non residue diets

TABLE I
Influence of Digestible Protein, Fat and Carbohydrate on the Volume of the Stool

Diet 7-day Periods	Protein	Fat	Starch	Sugar	Average 24-hr Volume of Stool		
					Subjects		
					K	McC	M
	gm	gm	gm	gm	gm	gm	gm
High protein	250	70-100	55-70	30-40	83	55	180
High sugar	50	100	135	365	222	205	329
High starch	50	100	400	100	193	121	253
High fat	50	300	75	25	126	118	211

which are from 90 to 95 per cent digested and absorbed, there is, nevertheless, a residue which reaches the bacteria-infested large intestine. The diet determines the character of this residue. That even small amounts of sucrose reach the colon is probable because of its relatively slower absorption rate² as compared to glucose and galactose. The putrefactive products of protein are probably, taken as a whole, costive in their effects. On the other hand the products of carbohydrate fermentation are the lower volatile fatty acids, lactic acid and carbon dioxide, which are definitely proved to be laxative³. Furthermore, it must be remembered, as emphasized by Kendall,¹ that bacteria will break down sugar in preference to protein for their energy needs. Thus, in the intestine just as in culture media, as long as food residues contain a certain amount of sugar, protein breakdown (putrefaction) is spared, i.e., reduced to a minimum. Thus a high carbohydrate diet has at least two effects:

(a) The products of sugar fermentation are laxative.

(b) The presence of sugar spares the breakdown of protein and thus minimizes the formation of costive products of putrefaction.

Table 2 shows that the volatile fatty acids in stools of normal men are increased by high carbohydrate diets and that the amounts of volatile fatty acids increase with the rise in stool volume. Pediatricians⁵ have long recognized the laxative nature of these acids and that their increased output accompanies sugar feedings to infants.

Lactic acid appears in cultures of almost all types of bacteria as long as there is abundance of sugar in the media. Pittman and Ohnsted⁶ could not demonstrate lactic acid in human stools. We interpret this finding as evidence of the remarkable symbiotic action of the many types of bacteria found in the intestine. Lactic acid incubated in raw fecal matter disappears.

Carbon dioxide and hydrogen are produced in largest quantities when sugar predominates in the diet. Physicians should realize that these gases are normal excretory products of bacterial fermentation. Many people and some physicians look upon the passage of flatus as an abnormal condition, whereas it is as normal as the passage of feces.

TABLE II
Effect of Diet (Non-Residue) on Total Volatile Fatty Acid Excretion

Diet	Average c c 0.1 N acid in 24 hours		
	Subjects

High protein	c c 90	c c 71	c c 179
High sugar	148	278	447
High starch	125	191	349
High fat	82	129	221

THE INDIGESTIBLE CARBOHYDRATES

When the physician is called upon to prescribe a diet as an adjunct in the treatment of constipation, he instructs his patient to take a "bulky" diet. He means by this that the diet should be rich in vegetables, fruits, and the bran of cereals. These foods contain indigestible carbohydrates which are supposed to pass through the upper intestinal tract unchanged and thus add to the bulk of the feces. The present conception of the action of bulky foods can be expressed by a quotation from Starling's "Textbook of Physiology"⁷ (p. 597): "The indigestible cellulose in the food is not without value. It has been shown previously that the peristaltic contractions of the intestine are roused primarily by the mechanical stimulus of distention. If the food is capable of entire digestion and absorption, the amount of feces formed is limited to that produced by the intestinal wall itself. The small bulk exercises very little stimulating effect on the intestine, and the

movements of the latter will therefore tend to be sluggish, especially in the absence of the mechanical stimulus determined by physical exercise. The presence of a certain amount of cellulose in the diet may therefore be of considerable advantage by giving bulk to the feces and ensuring the proper regular evacuation of the lower gut. It is probable that the constipation which is so common a disorder in civilized communities is due as much to the refinement in the preparation of food as to the prevalence of sedentary occupations incident on the working of such communities." The current belief, therefore, emphasizes the mechanical distention of the colon by bulky foods as the stimulus which prompts evacuation. The results of the experiments we are about to show suggest another important factor in addition to the mechanical one.

The indigestible portion of carbohydrate foods consists of the structural material of plants. Chemically it can be divided into three groups: cellulose, lignin, and hemicellulose. Cellulose is a polysaccharide which can be converted into glucose. It is insoluble in water, cannot be broken up by any of the enzymes of the mammalian intestinal tract, but can be broken down to glucose by the hydrolytic action of concentrated mineral acids. Lignin is an incrustation associated closely with cellulose and found in the harder portions of the structural parts of plants, especially in wood. The cellulose-lignin combination is dissociated by chlorine, sulphite solutions, strong alkalis and mineral acids. Lignin is not a carbohydrate. The hemicelluloses are a group of polysaccharides, soluble in dilute alkalis and for the greater part convertible into simple sugars by dilute acid hydrolysis. The sugars making up the major portion of various hemicelluloses are the pentoses (five carbon sugars), galactose, levulose and mannose. Although neither lignin, cellulose nor hemicellulose can be digested, nevertheless they all can be attacked by bacteria. If this were not so, our farm animals grazing on pastures would have great difficulty in maintaining their nutrition. In the intestinal tracts of herbivora bacteria convert cellulose and the hemicelluloses to much the same products as they do in the case of the soluble sugars and starches. It has been estimated that the grazing animal obtains as much as 25 per cent of his calories from the absorption of the fatty acids which bacteria produce by the fermentation of cellulose and hemicelluloses. Pringsheim⁸ has discussed this matter fully. These well known facts raise several very pertinent questions. Are cellulose and hemicelluloses broken down in the same fashion in the intestinal tract of man, and, if so, is the action of bulky foods mechanical or chemical? If bacteria do break down cellulose and hemicellulose to soluble products, how can their effect be a mechanical one? To what extent are cellulose, lignin and hemicelluloses broken down by bacteria in the intestinal tract of man? The literature does not contain satisfactory answers to these questions,⁹ because of the absence of satisfactory methods for determining quantitatively cellulose, lignin and the hemicelluloses.

If one studies an analysis of any cereal food product, he finds listed protein, fat, starch, ash, moisture and crude fiber. Crude fiber is the term used by analytical food chemists to denote the indigestible fraction of foods. The method for determining crude fiber goes back seventy years. It originated in the little town of Weende, Germany, and is known also as the Weende method. This procedure makes use of a double digestion, first with weak acid and second with weak alkali. Between each digestion the soluble products are filtered off and discarded. The crude fiber is what remains after these digestions. Chemists have long known that crude fiber represented merely an unknown fraction, varying with each material analyzed, of the combined cellulose, lignin and hemicellulose. Because the crude fiber method was completely unsatisfactory as a means of studying the amounts of indigestible residue in foods and feces, Williams and Olmsted¹⁰ published a biochemical method for the quantitative determination of each constituent of indigestible residue. It gave us the opportunity of conducting an experiment to determine the true action of bulky foods.

This experiment¹¹ was conducted with medical students. The materials fed were indigestible residues isolated from widely varying sources, concentrated by simple means which carefully preserved their essential chemical composition. Table 3 shows that 50 to 80 per cent of these

TABLE III
Analysis of Materials Fed

Materials added to basal diet	Wheat bran	Alfalfa leaf meal	Carrots	Corn germ meal	Cotton seed hull meal	Sugar beet pulp	Canned peas	Cabbage	Agar agar	Cellu flour
	%	%	%	%	%	%	%	%	%	%
Cellulose	16.9	32.5	23.2	15.8	19.4	34.2	35.0	29.5	0.0	78.8
Lignin	7.8	15.0	3.4	2.4	20.8	2.5	1.7	2.6	0.0	0.0
Hemicellulose	35.2	19.2	28.8	30.8	31.5	29.2	10.9	28.3	81.0	16.9
Starch, protein, ash, moisture and fat	35.7	32.7	40.6	49.7	17.5	30.3	49.5	37.1	8.5	3.1
Total	95.6	99.4	96.0	98.7	99.2	96.2	97.1	97.5	99.5	98.8

residues consisted of cellulose, lignin and hemicellulose, but that no two of these residues had the same composition. This affords opportunity for studying the relative effects of cellulose, hemicellulose and lignin. Before our experiment we did not know which of these three components was most important. We, therefore, maintained the amount of cellulose plus lignin constant (10 gm per day) and let the amount of hemicellulose be variable. To a basal diet of non-residue foods each residue was added for a period of six days. The stools were analyzed for volatile fatty acids, cellulose, lignin, hemicellulose and reducing sugars.

CRITERIA OF LAXATIVE ACTION

Obviously a material is not laxative merely because it increases the stool weight. If this were not so, inert materials recoverable 100 per cent in the feces would be considered laxative. We have found that certain materials of vegetable origin classed as roughage are almost completely recovered in the stools, do add to the weight of a basal stool but are quite constipating whether judged subjectively or by trauma to the colon. We adopted two criteria: (1) The impression of the subject as to whether or not the bowel movement was satisfactory. (2) The weight of feces over and above the weight of the residue recovered in the feces. For instance, if 70 gm of substance *A* were fed, 65 gm recovered in the feces and the weight of feces increased only 90 gm, this material could not be considered laxative. If, on the other hand, 100 gm substance *B* were fed, 29 gm recovered in the feces and the weight of feces increased 550 gm, this substance would be considered laxative.

As an index of true increase in stool weight we adopted a factor, termed "Increment in Stool Weight," which is obtained by subtracting from the stool weight of a residue feeding period the weight of residue passing the gut and the weight of a basal (residue free) period stool. This increment represents either increased free fluid content or water absorbed by the residue remaining in the stool.

RESULTS

Table 4 shows the increment in stool weights for seven days after these residues had been fed for six days. Basal stool weights were markedly increased in the cases of bran, carrots, corn germ meal, cabbage, agar and sugar beet pulp. Poor subjective results with only slight increment in stool

TABLE IV
Relative Effectiveness of Materials Fed

Materials Added to Basal Diet	Weight of Residue Fed	Increment in Stool Weight				Ratio Increment to Residue Fed
		Subject F	Subject W	Subject H	Average of F, W and H	
	gm	gm	gm	gm	gm	
Cellu flour	71.7	223	119	(-) 63	93	1.34
Cotton seed hull	105.9	104	123	66	97	0.91
Canned peas	74.5	114	255	134	167	2.24
Alfalfa leaf	79.5	182	318	221	240	3.04
Sugar beet pulp	93.4	662	372	171	401	4.29
Wheat bran	146.0	575	578	373	475	3.25
Carrots	106.8	700	589	336	541	5.06
Corn germ meal	154.4	590	563	581	578	3.74
Cabbage	101.5	647	781	449	625	6.15
Agar agar	80.2	835	719	445	666	8.30

weights are noted in the cases of cellu flour, peas, cotton seed hull and alfalfa leaf. These results take on significance when we compare the relative increases in stool weights with the chemical analyses of the residues. Table 3 shows these analyses. The cellulose varies in most of the materials between zero and 35 per cent, lignin between zero and 21 per cent, and hemicellulose between 10 and 35 per cent. In table 5 the characteristics of the chemical composition are stated very simply. Each material, which when fed resulted in a substantial increment of stool weight (essentially doubling of basal stool weight), is boxed.

TABLE V

Classification of Residues on the Bases of the Increase of Stool Volume and Their Chemical Composition

<u>High in cellulose</u>	{ Alfalfa leaf, beet pulp , peas cabbage and cellu
<u>High in lignin</u>	{ Alfalfa leaf, cotton seed hull
<u>High in hemicellulose</u>	{ Bran , carrots , corn germ meal , Cotton seed hull, beet pulp , Cabbage agar

A glance leaves not much doubt that when hemicellulose is high, the residue is apt to be laxative. Seven of these 10 materials fed proved on analysis to contain 30 per cent or more hemicellulose. Of these seven, six, when fed, resulted in a marked increment of stool weight.

Two materials contained 15 to 20 per cent lignin, the remaining materials contained only 1 to 3 per cent lignin. Alfalfa leaf and cotton seed hull, when fed, resulted in stool weights very little above the basal level.

Five of these residues were high in cellulose. That is, the analyses showed at least 30 per cent cellulose. Of these five, only two (cabbage and sugar beet pulp) resulted in marked increment of stool weight. Cellu flour was 79 per cent cellulose and when it was fed, the stools were of low weight. If cellulose were stimulating because of its mechanical bulk, one would expect cellu flour to be highly stimulating, but such is not the case.

From this analysis, we conclude that the comparison of these materials shows that when hemicelluloses predominate in the residue, the stool weights increase definitely, when lignin is present, in percentages as high as 20, the stools are increased above the basal level only to the extent of the material fed. Cotton seed hull was over 30 per cent hemicellulose. This level in other materials resulted in marked increase of stool weight but the 20 per

cent lignin present in cotton seed hulls apparently counteracted the effect of hemicelluloses. The explanation will be considered below.

DISAPPEARANCE OF INDIGESTIBLE RESIDUES

The analysis of the stools for lignin, cellulose and hemicellulose revealed a remarkably high percentage of disappearance of these substances during their passage through the human gut. Table 6 summarizes the disappear-

TABLE VI
Disappearance of Lignin, Cellulose and Hemicellulose

Residue Added to Basal Diet	Fractions of Indigestible Residue						Total Residue	
	Lignin		Cellulose		Hemicellulose			
	gm	%	gm	%	gm	%	gm	%
Wheat bran	1.9	10	11.4	30	29.8	35	43.1	30
Corn germ meal	*	*	29.5	57	59.5	63	89.0	60
Carrots	*	*	34.5	67	39.5	85	74.4	74
Cotton seed hull	3.7	12	4.8	14	10.6	30	19.1	18
Cabbage	*	*	29.8	55	33.1	80	62.9	80

Cellu flour	—	—	4.2	7	3.2	29	7.4	10

* Lignin content too small for valid results

ance of each material fed. Lignin was present in bran, cotton seed hull and alfalfa leaf in a considerable quantity. The stools passed during the feeding of these substances contained 88 to 97 per cent of the amounts fed. The lignin present in the other substances fed was so small that the high percentage disappearance, in our opinion, is of no significance. Lignin then is very resistant to bacterial attack. Cellulose disappeared to the extent of 7 per cent in the case of cellu flour, up to 67 per cent in the case of carrots. In six of the materials fed more than 45 per cent of the cellulose was lost during its passage through the intestinal tract. Apparently bacteria have little difficulty in attacking the hemicelluloses for they disappeared to a greater extent than either lignin or cellulose. In six of the 10 materials fed the total loss in this fraction was over 60 per cent. In the case of carrots, cabbage, beet pulp and peas over 80 per cent of the hemicellulose was lost. The summary of the total losses of indigestible residue show that in six of the 10 materials fed from 53 to 74 per cent disappeared as they passed through the intestinal tract.

The three materials resistant to bacteria (bran, cotton seed hull, and alfalfa leaf) contained considerable amounts of lignin. That foodstuffs high in lignin are resistant to bacterial degradation in the intestinal tracts of

farm animals is well known. In Germany during the war the delignification of straw was studied, and it was found that the treatment of straw with alkali, which broke up the association of lignin and cellulose, resulted in a material much more nourishing to herbivorous animals (see Pringsheim). In our experiments lignin was not broken down when present in considerable quantity and, furthermore, its presence prevented the breakdown of both cellulose and hemicellulose. It has been previously pointed out that no increase in volume of stools occurred after the feeding of the two materials highest in lignin, i.e., cotton seed hull and alfalfa leaf.

Cellu flour is a material produced (according to the manufacturer) by "hydrolyzing bleached fiber." In other words, it has been prepared in much the same way as crude fiber by the action of acid and alkali. We believe that this strong chemical treatment removes the portion of cellulose and hemicellulose which bacteria are able to attack and thus leaves it inert.

MECHANISM OF LAXATIVE ACTION OF INDIGESTIBLE RESIDUES

Since hemicellulose to a great extent and cellulose to a lesser degree disappear in passing through the human intestinal tract, they must be attacked by bacteria and if this be so, the metabolic products should be demonstrable. The products of carbohydrate residue breakdown are methane, carbon dioxide, hydrogen, alcohols and volatile fatty acids. Volatile fatty acids are easily determinable end products and are good indices of residue breakdown provided the soluble carbohydrate portion of the diet is regulated. Since these acids arise from the degradation of hemicellulose and cellulose, there should be a parallelism between the percentage of disappearance of those latter substances and the volume of volatile fatty acids recovered from the feces. Moreover since volatile fatty acids arising from any source (i.e. soluble or insoluble carbohydrates) are laxative, there should be a parallelism between the percentage disappearance of cellulose and hemicellulose, the stool content of volatile acids and the increment of stool weight. Table 7 shows this to be the case. The values are averages of three human subjects. The output of volatile acids formed after feeding those residues which were laxative exceeded those formed on high sugar diets.

In table 7 attention is called to the results in the case of agar agar. It was the most effectual of all materials fed in increasing the volumes of the stools. This substance is 81 per cent hemicellulose and therefore in comparison with the other types of indigestible materials fed, there should have been a greater percentage of the agar broken down and greater production of volatile fatty acids. That this was not so suggests that the effectiveness of agar is due to some other property which the other materials studied did not possess or possessed to a much less degree. The striking characteristic of agar is its ability to take up and hold water. It is this property which makes it such a fine foundation for culture media. The action of mineral cathartics is due to their ability to prevent the absorption of water by the

colonic epithelium Any food residue that is highly hygroscopic keeps the feces pliable and plastic and makes for their easy evacuation by peristaltic rushes If this explanation is correct, the hygroscopic property of the portion of food residues escaping bacterial degradation is of some importance and assists fecal evacuation The effectiveness of agar is by no means wholly due to its hygroscopic property Sixty per cent of the agar was broken down and the volume of fatty acids produced corresponded well with the amount of agar disappearing

In brief, an effective residue is one which is free from lignin, contains a preponderance of hemicellulose, is finely divided so that bacteria may break it down into laxative products and which after bacterial action yields a remainder with water binding properties ensuring a bulky, plastic, easily evacuated stool

TABLE VII
Relation of Increment in Stool Weight to Disappearance of Residue
and Recovery of Volatile Fatty Acids

SUMMARY

These researches into the physiology of bulky foods as represented by the 10 substances studied have led us to the following conclusions

Of the three classes of substances which make up the effective portion of indigestible residues, the hemicelluloses are the most efficacious in increasing the bulk of the stool Cellulose in its natural state is not as effective as the hemicelluloses (We suspect that highly hygroscopic residues may be very effective) Residues high in lignin are costive

Contrary to the accepted belief, the effectiveness of indigestible residues is not due primarily to the mechanical stimulus of distention but rather to chemical stimuli which arise from the destruction of hemicelluloses and cellulose by the intestinal bacterial flora One of these stimulating products is the lower volatile fatty acids There may be others

The chemical stimuli are aided by the hygroscopic quality of the residue escaping degradation. There may be other types of food residues in addition to the one studied here (agar) which are highly hygroscopic.

Finally we are well aware of other properties of foods that render them laxative. The effectiveness of the soluble juices of apples and pears and other raw fruits has never to our knowledge been accurately studied. Nor has the well known laxative quality of dried prunes and figs been identified. Certainly we have presented evidence for the stimulating effects of sugars and starches when they predominate in the diet.

The physician should be aware of all these facts and make use of them when he feels it is for the benefit of his patient that the volume of the stool should be increased.

OBSERVATIONS ON THE USE OF ACETYL BETA METHYLCHOLINE CHLORIDE IN CHRONIC ARTHRITIS ¹

By DOUGLAS BOYD, M D , STAFFORD L. OSBORNE, B P E , and DAVID E MARKSON, M D , F A C P , *Chicago, Illinois*

MANY investigators have studied the value of choline compounds in the treatment of conditions involving vascular spasm. Acetylcholine has long been known but, because of its nicotine-like action, is not suitable for therapeutic use. Major and Kline¹ synthesized acetyl beta methylcholine chloride, a more stable compound, free from the nicotine-like side effects of previous compounds. When Starr² compared the action of acetyl beta methylcholine with acetylcholine, he found they had similar effects on the cardio-vascular system of animals when given intravenously. He also found acetyl beta methylcholine chloride more than 10 times as active as acetylcholine when given hypodermically in normal man, and in addition it could be given orally. Moreover, it lacked many of the undesirable side effects of acetylcholine. Starr believes acetyl beta methylcholine to be a superior choline compound and that it should replace acetylcholine for therapeutic purposes.

The pharmacologic reactions due to acetyl beta methylcholine are prompt and vigorous, and are similar to those which follow stimulation of the parasympathetic nerves. There is well marked peripheral vasodilation. This latter action has been investigated as to its value in conditions accompanied by, or due to vascular spasm. We undertook this present problem to ascertain the effect of acetyl beta methylcholine on the peripheral circulation. A group of 25 patients from the arthritis clinic of Northwestern University Medical School was selected. Although we are not convinced that there is a causal relation between the circulatory changes in arthritis, and the joint lesions, we do know that circulatory disturbances accompany and aggravate the disease. This has been shown by Pemberton³ and others.

We realize the pitfalls attendant on the therapeutic study of this drug. This is particularly true in a field where measurement of success must depend on vague subjective changes and factors which are difficult to measure with accuracy. We have attempted to obtain objective measurements of observed changes after use of the drug, and to control these measurements under as nearly uniform conditions as possible, by identical observations on the same or similar patients on whom various types of therapy were used.

Acetyl beta methylcholine has been given to patients orally, subcutaneously and more recently by common ion transfer. When given by mouth the drug has a much milder effect and requires much larger dosage.

* Received for publication September 5, 1936

From the Departments of Medicine and Physical Therapy, Northwestern University Medical School, Chicago

than is suitable for subcutaneous administration Goldsmith⁴ gave 50 to 150 milligrams by mouth without profound or uniformly appreciable effect on the blood pressure or pulse rate Its action, when taken by mouth even in large dosage, was strikingly less effective than that produced by a 20 milligram dose given subcutaneously in the same patient

Acetyl beta methylcholine is prompt and vigorous in action when given subcutaneously Starin² states, "Its physiological activity is very great, being of an order similar to that of adrenalin or histamine" The striking systemic effects of the drug are a fall in blood pressure a rise in pulse rate, flushing of the face and neck, sweating and salivation This appears quickly, in one or two minutes after injection, and terminates in 15 or 20 minutes It produces a constricting effect on the bronchioles, and transient asthmatic attacks have been produced by this drug in those susceptible Its use also seems contraindicated in hypotension and in serious cardiac disease (except for its usefulness in attacks of paroxysmal tachycardia) In our series, we treated two cardiac patients, one of whom developed syncope and required atropine for relief, and the other suffered an aggravation of anginal pain The former patient had a chronic rheumatic carditis, the latter had a coronary lesion The drug should not be given intravenously because heart block may occur, particularly if the dosage is large (Katz⁵) Realizing this danger, we have not given acetyl beta methylcholine intravenously We have seen no evidence of heart block in this series, giving the drug by common ion transfer If untoward reactions do develop atropine abolishes the action of the drug almost immediately We have found it necessary to use atropine only once,—in the cardiac patient mentioned above

We gave acetyl beta methylcholine to our group of patients by the common ion transfer method, which in effect gives a slower, more gradual absorption from the superficial tissues The constitutional effect of the drug appeared and in addition there was obtained a striking local reaction consisting of increased skin temperature, sweating, gooseflesh, faster capillary flow⁶ and a diffuse pinkness of the skin over the area covered by the positive electrode This reaction, we feel, is quite different from and more lasting than that of local counter-irritation We feel that our controls (chart 1) demonstrate that it is definitely a local drug effect This local effect at times lasted for 12 to 24 hours We consistently found a decreased skin temperature distal to the treated area, whereas proximal to the treated area we always observed a rise in skin temperature of 2 to 4° F This makes it necessary, when local effect on the hand is desired, to apply the positive electrode on the hand itself and not on the forearm proximal to it (figures 1, 2, 3) These marked local effects furnish the rationale for the use of acetyl beta methylcholine in this manner in arthritis

We found that the drug consistently produced characteristic general reactions, which included a fall in blood pressure, averaging 12 millimeters of mercury and a rise in pulse rate averaging 22 beats per minute Respiratory rate was unchanged, but most patients described a sense of heaviness in

the chest and inspired deeper. A flushing of the face, neck and ears occurred in all who experienced general reactions. Perspiration was usually marked, particularly about the face and neck, even in those who claimed to have had no perspiration in several years. Increased salivation and occasionally

lacrimation lasted one to two hours. One patient had increased saliva after each treatment for 12 to 24 hours. Body temperature by rectum, taken by mercury thermometer and by thermocouple, showed no change.

The general changes described are similar to those which follow subcutaneous injection, with the striking difference, however, that the effects came more gradually, caused much less distress and lasted longer. For our purpose the added local effect was a distinct advantage.

The reactions noted are specific ones due to drug action and not to current or heat effect. We have used the same technic in the same patient without acetyl beta methylcholine and none of the characteristic effects ascribed to the drug were observed. Further attempts to control this were made by local use of diathermy, infra red, and by reversing the current with the drug under the negative electrode. In none of these did we produce any general reaction, and the local effect of these heating agents was obviously less in degree and of a more transient nature.

Technic. We used a vacuum tube rectified direct current which gave a fairly smooth galvanic current (figure 4). The active electrode consisted of an asbestos fabric (resistant to tears) saturated with a 1 per cent solution of acetyl beta methylcholine chloride. Lower concentrations of the drug were tried, but we did not obtain satisfactory reactions with less than a 1 per cent solution. Kotkis and his associates,⁶ working with dogs, reported no difference in drug effect with 1-1000, to 1-8000 solutions. They did, however, cover a relatively larger percentage of the skin area but did not mention the effect of stronger (1-100) solutions. We found a decided difference between the reactions obtained with a 1-100, and with a 1-200 solution. The weaker solution gave none of the clear-cut reactions illustrated in figures 1 and 2. The saturated fabric was wrapped in close contact about the part to be treated, and then a metal foil strip, three-eighths of an inch in width, was wound spirally about the saturated paper (figure 4). This metal strip was used to conduct the galvanic current evenly over the whole area. The positive pole of the galvanic current source was connected to the distal end of the metal strip. The negative pole of the machine was connected to the patient's back by means of a large dispersive electrode, 10" by 12" in size. This completed the circuit. The strength of current and the time of the current flow regulates the effectiveness of the ionization. We fully realize the limitations of introducing ions into living tissues by this method. Individual tolerance to the treatment guided us somewhat in the current strength, but we were usually able to give 40 to 50 milliamperes for 20 minutes after the first treatment. When the treatment was started, the current strength was gradually raised until the desired milliamperage was reached. Sudden increases should be avoided. At the end of treatment, the current intensity was gradually reduced until no current flowed. Following treatment the patient should remain quiet and warm for 30 to

60 minutes and then be allowed to resume his usual activities. When many joints are involved we have found it better to concentrate treatment on one joint or limited area,—such as the hand. The most satisfactory

FIG 4 Method of applying negative (above) and positive (below) electrodes for ionization of acetyl beta methylcholine

interval between treatments appeared to be three or four days. The therapeutic effects on patients were studied after five, 10, 15, and 20 to 25 treatments. As a result of this check, we found the maximum effect was achieved after 18 to 20 treatments.

Acetyl beta methylcholine can produce undesirable reactions. Dosage when given subcutaneously must be accurate. One physician gave a subcutaneous dose of 250 milligrams of acetyl beta methylcholine which was 10 times that recommended as maximum. His patient had a severe reaction, but survived. Regardless of how this drug is given a hypodermic of atropine gr 1/100 should always be prepared and available for use. Heart block can easily be produced in dogs, but they usually recover without atropine. These unfavorable reactions are minimized when the drug is given by common ion transfer. We have not had any very serious reactions, nor have we heard of any fatalities from its use. It is a drug of quick, powerful reactions, however, and should be as much respected as epinephrine.

We have treated 27 patients in the manner described during the past two and one-half years (chart 3). Earlier we made no attempt to select patients, as to the stage or type of their arthritis. It was soon evident, however, that certain less advanced arthritics derived more benefit than the far advanced. One would expect this, and it proved to be true in both the rheumatoid and osteoarthritic patients. Those with evident circulatory disturbances of the extremities—those with cool, pale, moist, and often cyanotic hands and feet—seemed to gain most from the treatment. All of our patients had had considerable previous medical treatment along the usual lines without much evident improvement. Acetyl beta methylcholine is not useful in those arthritic patients with peripheral arteriosclerosis nor is it feasible to treat patients with well distributed skin changes. It seemed most helpful in those who (1) show the earlier changes of the rheumatoid type, with cool, damp and cyanosed extremities, (2) have moderate hypertrophic changes with paresthesias and sensitivity to cold, and (3) have sciatica or other manifestations of spinal nerve root irritation as a result of spinal arthritis.

In an attempt to gain objective evidence of the changes taking place, we have measured the pulse volume waves in the limb under treatment. These pulse volume wave changes were recorded graphically by the Johnson plethysmograph (chart 1). The graphic records, taken on the fingers before and after treatment of the hands, show an increased wave deflection, which is apparently dependent on the ability of the blood vessels in the studied part to dilate with each heart beat. Many cases of arthritis thus studied showed a surprisingly flat wave, as is illustrated in chart 2. One patient with a well marked peripheral arteriosclerosis showed a very small pulse volume wave both before and after acetyl beta methylcholine. Usually, however, the dilation of the vessels, as measured by the pulse volume wave, was increased after application of the drug (figure 5). We tried to keep conditions of the room and patients uniform in taking records. Although we did not have a constant temperature air-conditioned room, room temperature was taken into consideration. We consider this pulse volume wave record a better index of improved circulation in an arthritic member than observations of capillary changes in the nail fold. We do not believe that

a convincing characteristic capillary bed picture has been presented in arthritis

Many patients showed not only a marked pulse volume wave increase in the member treated locally by common ion transfer but also minor increases in pulse volume wave in the opposite untreated member. Arthritics with cool, clammy hands showed in the first instance an almost flat curve, and

FIG 5 Pulse volume wave of index finger (A.M.) before (I) and after (111) acetyl beta methylcholine applied to the hand

after acetyl beta methylcholine a striking increase in the waves (figure 5). Given subcutaneously, the drug did not cause local changes in circulatory volume.

In the patients on whom control observations were made, the pulse volume waves were of a lower amplitude.

The well known cycles of improvement of arthritics and the lack of any well-defined measurable factors, make evaluation of therapy hazardous.

The recording of decreased pain and increased motion in function rests too largely on the patient's interpretation of his subjective sensations. With patients under continuous observation one can judge fairly well the extent of clinical improvement, but this rather intangible judgment is difficult to present to others. Nevertheless, we can offer no better measure for evaluating the present group.

The hands treated showed in 8 of the 14 patients an increased flexibility in function and usefulness in work. A patient, for example, who previously had been able to lift her coffee cup to her mouth only by using both hands, was able to do this with one hand in a normal manner. Another, forced to give up her work as a clerk and unable to do sewing, became able to work and sew again four days a week without discomfort for continuous periods of an hour or more. A young woman with considerable pain, stiffness and weakness in her hands who had been unable to do her housework for two years, reported a decided decrease in joint pain, improved motion, and a marked increase in strength. She became able to do all her housework except scrubbing floors and ironing. An older woman with lumbar and sacro-iliac arthritis, who complained of aching pains and constant fatigue to such an extent that she was comfortable only in bed, was treated over the area of her discomfort with the usual general reaction. After treatment, the low backache largely disappeared, "she felt quite strong again and was not so tired." Four months later without further treatment, she was much stronger, and without undue fatigability. A medical student observed an increased flexibility of the hands, a loss of considerable morning fatigue and joint stiffness, became much less tired and resumed walking and other outside activities. He noted the effect of the drug for three or four days following each treatment.

The group of failures in treatment were in general the elderly, far advanced rheumatoid arthritics with bone changes and fibrosis. In such advanced degrees of the disease much relief cannot be expected.

Striking relief of pain was afforded some cases, but as a record of therapeutic achievement in this respect, our results are only fair (chart 2). The striking therapeutic effect in the group is the decreased fatigability, and the increased endurance. This was consistently noted in almost all patients who absorbed the drug and took a sufficient number of treatments. Several patients resumed their normal activities, spent less time in bed, and carried on more work and play without increase of pain, stiffness or fatigue. This improvement in the endurance of our patients was called to our attention voluntarily and spontaneously, it being an unanticipated effect. We have not noted such a relief from fatigue under other forms of treatment. That this is a vital factor in the lives of most arthritics is constantly borne out by the complaints of most patients. Most workers in this field agree that rest sufficient to relieve fatigue is a most important element in the treatment of arthritic patients.¹⁰

Acetyl beta methylcholine does relieve fatigue in a large percentage of arthritic patients who are able to take adequate dosage. Whether this is due to its vasodilator effect, or some more direct effect on muscle, we do not know.

It is interesting that Hench¹¹ and his associates at the Mayo Clinic have treated this fatigue factor with amino-acetic acid and ephedrine. They report striking effects in certain patients, no effect at all in other apparently similar cases. No satisfactory measure of such fatigue has been proposed, though indirectly metabolic studies may help. It has not yet occurred to us how this factor may be measured. We believe that if fatigue can often be controlled, in many instances pain can be relieved, physical activity increased, and the morale of these patients raised considerably. It is this effect of mecholyl that impressed us most, and the prevalence of so many tired, physically restricted arthritic patients makes the continued use and study of the drug worth while.

CONCLUSIONS

1 Twenty-two cases of arthritis have been treated with acetyl beta methylcholine common ion transfer.

2 Eight of 14 patients whose hands were treated showed an increased flexibility in function and usefulness in these hands.

3 Pain was relieved in some cases.

4 Muscular fatigue was markedly relieved in almost all cases adequately treated.

5 Increased endurance was experienced by those completing the course of treatments.

6 Circulatory changes were graphically shown.

7 The group of failures were in general the elderly patients with far advanced rheumatoid arthritis with bone changes and fibrosis.

8 Patients with circulatory disturbances of the extremities, those with cool, pale, moist, and often cyanotic hands and feet gained most from treatment.

9 Maximum effects were gained after a series of 18 to 20 treatments.

STUDIES IN HODGKIN'S DISEASE

III CLINICAL APPLICATION OF THE GORDON TEST (A SYNDROME OF ATAXIA, SPASM AND PARALYSIS INDUCED IN RABBITS BY THE INTRACEREBRAL INJECTION OF EMULSIFIED HODGKIN'S TISSUE)'

By EARLE M. CHAPMAN,[†] *Boston, Massachusetts*

THE description by Gordon^{1,2} in 1932 of a biological test for Hodgkin's disease aroused widespread interest. Van Rooyen³ in Scotland made a trial of the test and later, in a paper published in this country, van Rooyen and Olgivie⁴ expressed the opinion that it had proved itself to be of definite clinical value. Our own evaluation of this test as a diagnostic aid in the differentiation of the Hodgkin's type of lymphoblastoma is presented here after three years of experience in which material from 16 cases of Hodgkin's disease and 30 cases of other types of lymphadenopathy has been tested.

Gordon's test consists of the injection of a saline or broth emulsion of lymph node tissue into the cerebrum of the rabbit. A positive test appears three or four days after such an injection when the animal loses weight, develops ataxia, stiffness of the legs and neck, spasticity and has convulsions on stimulation. If the animal survives, these signs of cerebral disease may disappear in two to four weeks leaving it quite normal, again animals may survive for weeks in the chronic active state and gradually develop paralysis of the hind quarters or even a quadriplegia. The above syndrome is not peculiar to the rabbit alone, nor is the reaction specific for Hodgkin's tissue. Kelser and King¹¹ have obtained a similar response in the guinea pig using both bone marrow and Hodgkin's tissue, and Friedemann⁵ has pointed out that the proteolytic ferment of Jochmann⁹ and his own acetone-alcohol-ether extract of normal human spleen, bone marrow or leukocytes may provoke a similar reaction.

METHODS

The specimens were obtained personally at operation, placed in a sterile Petri dish and taken to the laboratory. Here the extracapsular tissue was cleaned away under aseptic precautions and a transverse section, usually including one-third of the node, was removed for routine pathologic section. Another third of the node was cut with scissors into small bits and the tissue ground in a mortar with sterile normal saline or meat broth of pH 7.4. This heavy emulsion (approximately 15 per cent) was then cultured on aerobic and anaerobic media and part of the supernatant fluid

* Received for publication August 27, 1936

From the Department of Pathology and the X-Ray Treatment Clinic

† Dalton Scholar, Massachusetts General Hospital, Boston, Mass

immediately injected into the brains of rabbits. Cultures of the emulsions usually showed no growth but in a few, colonies of staphylococci or common contaminants appeared. Pure broth cultures of these organisms when injected into rabbit's brains did not produce a positive test. The remaining third of the lymph node and the unused portion of the emulsion were then stored at 5 to 10 degrees Centigrade.

Injection of the rabbit was done under ether anesthesia. With a small two-edged hand tool the skull was trephined at the angle formed by the junction of the occipital and central longitudinal ridge. This exposed relatively silent areas of the occipital lobe into which 0.35 to 0.45 c.c. of the emulsion was slowly injected. The skin wound was closed with Michel's clips and the animal returned to the cage. Following this the animals were weighed daily and watched for signs of a positive test.

Extracts of biopsied nodes and of bone marrow, liver and spleen obtained at autopsy were also made, using the method described by Friedemann.⁵ The tissue was extracted in a mortar with acetone and at the end of 15 minutes the undissolved material was collected on filter paper and washed first with absolute alcohol and then with ether. The residue was allowed to dry and then mixed with an equal volume of 33 per cent glycerin in saline. After standing 24 hours the undissolved material was spun down and the supernatant glycerin mixed with five times its volume of a 2:1 alcohol-ether mixture. The resulting precipitate was allowed to settle out and then taken up in saline for injection.

RESULTS

Table 1 shows the control series including lymphosarcoma, reticulum cell sarcoma, lymphoblastoma type undetermined, giant follicular lymphoma, hyperplasia, chronic inflammation, metastatic epidermoid carcinoma, mixed

TABLE I
Tissues Used as Controls for Gordon's Test

Diagnosis	Number of Cases	Rabbits Injected	Gordon's Test
Lymphosarcoma	10	20	20 Negative
Reticulum cell sarcoma	5	10	10 "
Lymphoblastoma? type	1	2	2 "
Giant follicular lymphoma	1	2	2 "
Hyperplasia	4	10	9 "
Chronic inflammation			1 Positive

Mixed tumor of parotid	3	6	6 "
Dermoid cyst	1	2	2 "
Fetal tissue	1	2	2 "
Pseudo tumor of orbit	1	1	1 "
	32	65	64 Negative 1 Positive

tumor of the parotid, dermoid cyst, fetal tissue and pseudo-tumor of the orbit. In all, 65 rabbits were injected with material from 32 patients. In only one case was a positive test obtained. This was from an emulsion of a lymph node from a seven year old girl who had an enlargement of the cervical and inguinal nodes for three years. The clinical impression was that she had Hodgkin's disease and, therefore she had received roentgen-ray treatment two years before entry. The nodes then decreased in size but had enlarged again during the year previous to coming into our clinic. A biopsy was done in the hope of establishing a diagnosis of lymphoblastoma but the pathological report was hyperplasia. Of three rabbits injected two remained normal while the third developed a weakly positive test. The diagnosis in this case is still uncertain, but 10 months after biopsy she was clinically in the end stages typical of Hodgkin's disease. Except for this case and one case of reticulum cell sarcoma the patients in the control series had received no roentgen-ray therapy before biopsy of the lymph node.

Gordon² remarked that this encephalitogenic agent was diminished or absent in fibrosed Hodgkin's glands but van Rooyen,³ with whom we agree, could find no significant differences in the histologic structure of nodes giving a strong, weak or negative test.

Table 2 summarizes the results of tests with material from 16 untreated patients whose biopsied lymph nodes showed the histologic appearance typi-

TABLE II
16 Hodgkin's Tissues Used in Gordon's Test

	Number of Cases	Rabbits Injected	Gordon's Test	
			Positive	Negative
Cases having at least one positive test	9	58	46	12
Cases having all negative tests	7	21	0	21

cal of Hodgkin's disease. These 16 patients entered the hospital for the diagnosis of enlarged lymph nodes, often in one or both sides of the neck. They were usually young people (average age 26 years) who had noted the appearance of the masses from one month to two years before entry (average duration 5 months). In nine (56 per cent) of these cases the tests gave results which were considered positive while in seven the results were negative. However, in five of the nine one or more of the injected rabbits showed no reaction. In the other four cases all animals were positive. Van Rooyen⁴ reports 75 per cent of all Hodgkin's cases as giving a positive test while Hanson⁷ and van der Hoeden and Hulst⁸ each report 60 per cent. Goldstein¹² found the test positive in seven of nine cases of Hodgkin's disease.

It is of interest at this point to note that in none of the other types of lymphoblastoma was a positive test obtained, in contrast to the finding of positive tests in over half the cases of the Hodgkin's type. This lends support to the belief that Hodgkin's disease may be separated from the lymphoblastoma group as a distinct entity.

THE NATURE AND PATHOLOGY OF THE ENCEPHALITOGENIC AGENT

The properties of the agent producing these reactions in the rabbit have been investigated by Gordon,¹ MacKenzie and van Rooyen⁶ and Kelser and King¹¹ and our observations here are in accord with theirs. Transmission of the agent from rabbit to rabbit was not effected and repeated injections of inert material did not sensitize rabbits to later injections of Hodgkin's material that had proved to be negative in rabbits that had not been previously injected. Evidently no immunity to the agent was produced as animals rendered positive and allowed to recuperate again became positive on injection of a second active emulsion. Likewise the serum of previously positive animals when added in equal quantities to an active emulsion did not inhibit the encephalitogenic factor.

The agent is remarkably stable. After preservation for 24 and 26 months at 5 to 10 degrees Centigrade and being considerably desiccated, two Hodgkin's nodes were emulsified and produced definitely positive Gordon tests. After exposure to 70 degrees Centigrade for one hour the agent loses its activity. The active principle is extracellular as cell free supernatant fluids give positive tests. The agent in saline emulsions could not be passed through a filter (Berkefeld N) and application of the emulsion to the scarified cornea of rabbits provoked no signs of either encephalitis or keratitis. Recently van Rooyen⁶ has found that the maximum effect of the agent is obtained if the broth is adjusted to a pH of 6.8 to 7.3 and that by so adjusting the Seitz and Berkefeld candles he could successfully pass the agent through the filter. It is well known that meat broth itself will change the retentiveness of a Berkefeld filter,¹⁰ so that this may in part explain his results.

Friedemann⁵ recalled that this reaction of the rabbit after the injection of Hodgkin's gland emulsion was not specific, as Jochmann and Lockemann⁹ had found a proteolytic ferment in extracts of normal spleen, white blood cells and bone marrow of man and monkey that produced identical effects in rabbits. Friedemann's modified technic, the acetone-alcohol-ether extract described here under methods, has also yielded an encephalitogenic factor that produces positive Gordon tests. Friedemann assumed that a virus or bacteria could not withstand such processing, but MacKenzie and van Rooyen⁶ have since found that it is not necessarily lethal to certain bacteria. In addition to the tissues mentioned above we found that such an extract of normal human liver would produce a positive test.

From two cases of Hodgkin's disease both the broth emulsions and the acetone-alcohol-ether extracts of diseased nodes gave typical positive Gordon tests while from a third case neither caused a reaction in the rabbits. From three control cases (reticulum cell sarcoma, lymphosarcoma and lymphoblastoma type undetermined) neither the emulsions nor the extracts caused any reaction in rabbits.

The exact nature of this agent is still unknown but as shown above it lacks many of the characteristics of a virus. Gordon mentioned the similarity of the reaction to the meningo-encephalitis produced by the virus of dermo-vaccine, herpes and psittacosis and the remarkable stability, like the virus of swine fever. In a recent publication MacKenzie and van Rooyen⁶ found that the proteolytic ferment of Jochmann could be identified separately from the agent obtained by the methods of Gordon and Friedemann. As indicated in the six cases last mentioned the agent can withstand rather drastic extraction with acetone-alcohol-ether and what is more important, it is not present in lymph nodes giving a negative Gordon test.

Autopsies were done on rabbits killed with ether. Those found dead in their cages were not examined. The brains usually appeared normal in the gross except for some hyperemia about the site of injection, although in two gross signs of meningitis were found. Cultures of the injected areas yielded no growth and no evidence of the parasite *Encephalitozoon cuniculi* could be found. Microscopic examination showed changes, usually in one or both hemispheres. A perivascular infiltration of mononuclear cells resembling monocytes and lymphocytes was the predominant lesion but meningeal infiltration and occasional focal collections of these large mononuclear cells were observed. While these changes were observed in all the positive cases they were very slight in three animals and a slight meningeal reaction was present in several of the negative ones. Consequently it is felt that no definite conclusions can be drawn as to the significance of the findings. One can probably go so far as to say that the changes observed, because of the inconspicuous microglial reaction, do not resemble the picture commonly found with virus diseases of the brain. The histo-pathologic aspects of the problem invite a more thorough examination of positive animals and careful comparison with a larger number of injected negative and untreated animals.

SUMMARY

From nine of 16 cases (56 per cent) of microscopically typical Hodgkin's disease positive Gordon tests were obtained, but of 58 rabbits injected with material from these nine there were 12 rabbits that showed no reaction. In a control group of tissues from 32 cases of other pathological conditions 31 gave negative tests. In the one control case described the patient may have had Hodgkin's disease and yet two of the three rabbits injected were negative. The encephalitogenic agent which produces this response in the rabbit is not specific for Hodgkin's tissue for it may be extracted from nor-

mal human marrow, spleen, liver and leukocytes. It was not obtained from eight lymph nodes showing hyperplasia or chronic inflammation. Knowledge of this agent is limited but it appears that it is not a virus and as it will withstand acetone-alcohol-ether extraction it may be a non-living substance simply acting as a profound irritant to nerve tissue.

CONCLUSIONS

Gordon's test, if positive, is only of supportive aid in the diagnosis of Hodgkin's disease and if negative does not exclude it. Therefore, this test should not replace the routine pathologic examination of tissue for diagnosis. The absence of the encephalitogenic agent in the first four types of lymphoblastoma (lymphosarcoma, reticulum cell sarcoma, giant follicular lymphoma and lymphoblastoma type undetermined) adds support to the belief that Hodgkin's disease is a separate clinical and pathological entity.

The author is indebted to Miss Helen Roach for technical assistance and to Dr Chas S Kubik for reviewing the pathology of the brain lesions.

THE COURSE OF HYPERTENSIVE HEART DISEASE

I AGE OF ONSET, DEVELOPMENT OF CARDIAC INSUFFICIENCY, DURATION OF LIFE, AND CAUSE OF DEATH

By NATHAN FLAXMAN, M D , *Chicago, Illinois*

ARTERIAL hypertension is the most common cause of heart disease in adults regardless of race or sex.¹ There has developed in the last two decades especially an overwhelming literature devoted to this subject which, as Crummer² states, has almost buried from our modern view the earlier and fundamental observations. Janeway's³ classical analysis of 870 cases of hypertensive cardiovascular disease (nephritis included) first indicated that the most prominent symptoms associated with hypertension are circulatory and that in the presence of early symptoms of myocardial weakness a better than 50 per cent chance existed that death eventually would be due to myocardial insufficiency. Fahn,⁴ who added greatly in these earlier days to our knowledge of hypertensive heart disease, found that arterial hypertension by its direct or indirect effects on the heart muscle was the chief etiologic factor in approximately three-fourths of the cases of so-called chronic myocarditis.

The present study on the course of hypertensive heart disease was begun on December 31, 1931. In the following four years 1170 cases of hypertensive heart disease were examined and their histories carefully analyzed. Cases with complicating heart disease of other origin such as those with lesions due to syphilis, rheumatic fever, or thyrotoxicosis, or hypertension the result of glomerulonephritis, and cases with insufficient data were excluded. There remained for analysis 623 uncomplicated cases of hypertensive heart disease. The criteria followed for the diagnoses were those approved by the American Heart Association.⁵

The exact duration of the essential hypertension was not known in any of the cases. Only 31 patients (3.7 per cent) had known of the existence of their hypertension for from one to 12 years prior to the onset of symptoms. In this group the average known duration was five years.

The symptoms that indicated the onset of hypertensive heart disease were dyspnea, precordial or epigastric pain or both, palpitation, weakness, persistent indigestion, and marked loss in weight. Only 6.6 per cent of the white patients were below 40 years of age at the onset of symptoms, but 16.6 per cent of the colored patients were below that age (table 1). The largest incidence among the colored patients occurred in the decade from 41 to 50 years (47.6 per cent), while among the white patients the highest incidence fell in the sixth decade, 51 to 60 years (49.7 per cent).

and of the deceased colored patients 84.5 per cent had died within two years after the onset of symptoms. A comparison with the percentage of living patients who were observed within two years after the onset of symptoms indicated the same ratio, 77.6 per cent of the living white and 82.1 per cent of the living colored patients. The only similar figures available for comparison are those of Janeway³ who reported that the average duration of life in his group of well-to-do patients after the onset of symptoms was four years in men and five years in women.

The symptoms were usually slowly progressive after an insidious onset but the numerous exceptions made attempts to estimate prognoses very difficult. The life-expectancy was short when the symptoms appeared suddenly and were not preceded by any omens of cardiac distress. The average duration of symptoms before the occurrence of heart failure was one year. The main reason for the short interval between the onset of symptoms and the appearance of congestive heart failure appeared to be the sufferers' reluctance to seek available medical attention for the relief of symptoms. Many of the patients continued to work and struggle along in spite of evident heart failure. Some delayed going to bed until the symptoms of failure became so pronounced that they no longer could stand on their feet. Such unnecessary delays led to the death of patients early in the course of the disease.

A comparison of the duration of the disease after the onset of congestive heart failure in the known deceased and in the living patients indicates approximately similar percentages (table 3). Of the deceased white 89.2 per

COMMENT

Since an analysis of the course of hypertensive heart disease might not be fairly representative if it were based exclusively on data from the records of deceased patients, there has been included in this study comparative figures drawn from the records of living patients

The short duration of life (two years or less in approximately 80 per cent of the deceased patients) may be accounted for in part by the fact that in the class of patients studied medical attention was not sought until the disease had made marked headway. Janeway, whose series included chiefly patients from the well-to-do, stated that one-half of the whole number of the deceased died within the first five years, one-fourth lived between five and 10 years, and the remaining one-fourth lived over 10 years. Because of the striking variations in the duration of the disease he advised great caution in prognosis. In this series of cases eight deceased patients had lived five to 10 years after the onset of symptoms and we found 26 patients who were living after five to 10 years. Two deceased patients had lived, and seven patients are living 10 to 20 years after the appearance of symptoms.

Two of the deceased patients had lived longer than five years after the onset of congestive heart failure, and at the conclusion of the study there were seven patients living five to eight years after the first appearance of congestive failure.

SUMMARY

The course of hypertensive heart disease based on a four year study of 623 uncomplicated cases (189 known dead and 434 known living) is reported. Approximately 80 per cent of the deceased succumbed within two years after the onset of symptoms. Congestive heart failure occurred most frequently within one year after the onset of symptoms, and 85 per cent of the deceased had died within one year after heart failure appeared. The majority of the deceased colored patients (65.2 per cent) died before 50 years of age, while a minority of the deceased white patients (30.2 per cent) succumbed before that age. Sixty-five per cent of the deceased died of congestive heart failure, although all of the patients had evidence of heart failure at some time during the course of the disease or at the time of death.

A significant number of patients, although very small in comparison with the remainder, had lived or are still living five to 20 years after the appearance of the first symptom, and a lesser group had lived or are living five to eight years after the occurrence of congestive heart failure.

It is a pleasure to express my indebtedness to Dr. Italo F. Volini from whom much encouragement to carry out this study was derived.

* Submitted for publication October 14, 1936

This Third Rheumatism Review was prepared at the request of the American Association for the Study and Control of Rheumatic Diseases. The editorial comments express the opinion, not of the Association but of its editorial committee (the authors of the Review) of which Dr. Hench is Chairman.

DURING 1935, medical literature published in English contained over 600 articles on diseases of joints and related tissues and on allied subjects, which have been surveyed for this Third Rheumatism Review. This number is a substantial increase over that of previous years, an increase due in part to the greater amount of investigative work being reported, but particularly to the number of short synopses and reviews presented by physicians to county and state societies. Making few or no pretensions to original researches, many of these papers contained little suitable for this review. But they have a significance not to be overlooked. For the most part they reflect a sound, broadened view of the problem of rheumatism, and provide definite evidence of the growing interest of the medical profession therein. The general practitioner is no longer willing to ignore rheumatism, content with the sorry gesture of salicylates for his new, and spas for his old, arthritic patients. His mind is in ferment, his interest is aroused. His is now a more resolute inquiry, increasingly purposeful and critical. The slogan of the few is becoming that of the many. Something must be done to solve the enormous problem that is "rheumatism."

GENERAL INCIDENCE AND OCCUPATIONAL DISTRIBUTION

Statistics given in previous Reviews^{1,2} show all too well how great a social and economic problem rheumatic diseases are creating. Rheumatic fever and "nonspecific arthritis" were found to be "world problems" in a recent survey on "The Geography of Disease" by the Division of Medical Sciences of the National Research Council.³ Rheumatism apparently knows no boundaries of climate or geography, and few indeed are the countries not widely affected thereby.

Occupational factors play a definite rôle in the incidence of rheumatic diseases, but statistics on the relation of industrial environment to the incidence and course of these diseases have generally been inadequate, according to Buckley,⁴ because neither the patient's occupation nor the exact type of his disease has been carefully classified. Buckley noted that coal miners and others who work underground at warm temperatures and high humidities are much (50 per cent) less subject to atrophic and hypertrophic arthritis than the general male population of Buxton, England, but are much (50 per cent) more prone to fibrositis. Stokers and others engaged in "hot occupations" seem much less susceptible to atrophic or hypertrophic arthritis, rheumatic fever, or fibrositis, but seem prone to gout. Of those reporting to the Devonshire Hospital because of "rheumatism," 8 per cent had gout. A possible cause was considered to be loss of perspiration, an altered saline content of tissue, and changes in the solubility of sodium bismurate. Outdoor workers suffer oftener from atrophic arthritis and from rheumatic fever, indoor workers from hypertrophic arthritis and from fibrositis.

CLASSIFICATION OF DISEASES OF JOINTS AND RELATED STRUCTURES

A general familiarity with terms used by various writers is the first step toward a universal classification of rheumatic diseases. By this token the year's literature indicates some progress. Although writers have continued to use favorite designations, they have with increasing frequency appended the synonyms of others, indicating familiarity therewith. Some have adopted the classification used in our previous Reviews which embodies that approved by the American Committee for the Control of Rheumatism. The year's crop of "new classifications" is small. In general they are but minor modifications of old classifications, or are sometimes proposed without adequate clinical or pathologic foundation to invite our acceptance of them. None seems subject to less criticism than that used in our previous reviews. Hence they will not be copied here to add to the reader's confusion.

Diseases of joints and related structures may be briefly classified as follows: (1) those due to trauma, (2) those due to infections of known type, (3) those of unknown cause but possibly, or probably, due to infection or related toxins, for example, rheumatic fever, atrophic (infectious, proliferative, rheumatoid) arthritis, (4) those of unknown cause and of which the chief characteristic is degenerative change in tissue, for example, hypertrophic (senescent, degenerative, osteo-) arthritis, (5) those of which the chief or only obvious characteristic is some recognizable chemical derangement—a none too well defined group which includes gouty and hemophilic arthritis and the arthritis of serum sickness as well as certain forms of arthritis called "chemical," "metabolic," "allergic," "endocrine," and (6) a miscellaneous group of unclassifiable types. For a detailed amplification of this classification and our own criticism of it and of other classifications the reader is referred to the first review.¹

It would be advantageous for physicians of at least the two great English-speaking nations to employ the same classification. To this end the provisional classification adopted by the Subcommittee on Nomenclature of the British Committee on Chronic Rheumatism is given herewith, and attention is called to their excellent first Report⁵ which includes a full discussion of the pathologic criteria used for this classification.

Group 1 Rheumatic fever, acute (Syn. "Acute Rheumatism") or subacute

Group 2 Acute gout

Group 3 Chronic arthritis

A Rheumatoid type ("atrophic, proliferative")

1 Specific causation Known etiology

(1) Gonococcal arthritis

(2) Tuberculous arthritis

(3) Syphilitic arthritis

(4) Arthritis following other specific infections such as dysentery, scarlet fever, rheumatic fever

2 Nonspecific causation Unknown etiology

(1) With known associated factors

(a) Metastatic or "focal" arthritis, including so-called "multiple infective arthritis"

(b) Associated with disordered metabolism (e.g., gout)

(c) Climacteric arthritis (villous type)

(2) With no known associated factors

(a) Classical type of rheumatoid arthritis of women, usually of child-bearing period

(b) Rheumatoid arthritis in children, including Still's disease

The term "rheumatoid arthritis," when utilized, should be confined to the above two conditions, all other forms being designated "rheumatoid type"

B Osteo-arthritic type ("hypertrophic", "degenerative")

1 Known etiology

(1) Secondary to trauma

(2) Secondary to arthritis of rheumatoid type

(3) Associated with disordered metabolism (climacteric, gout, scurvy, hemophilia)

(4) Associated with organic disease of the nervous system (e.g., Charcot's joints and syringomyelia)

2 Unknown etiology

So-called "senile variety" (e.g., morbus coxae senilis)

Group 4 Non-articular rheumatic affections

DISEASES OF ARTICULAR AND PERIARTICULAR TISSUES RELATED TO TRAUMA

Acute trauma or prolonged or repeated trauma may initiate reactions in articular and periarticular tissues resulting in either an arthritis, synovitis, tendinitis, bursitis, or myositis. The type and extent of the reaction depends on the nature, location and severity of the injury, and resistance of affected tissues and their powers of regeneration. The reaction to trauma to synovial tissue, which has high regenerative powers, will not be the same as that to cartilage, which has feeble powers of regeneration. Trauma may produce arthritis in a previously healthy joint, or it may aggravate a pre-existing arthritis. These two types of traumatic arthritis should be differentiated.

Articular Disease Due Primarily to Trauma When an injury is promptly followed by an acute reaction of swelling, redness, stiffness, muscle spasm and within a relatively short time by roentgenographic changes, a diagnosis of traumatic arthritis is obvious. Diagnosis may be difficult when a delay elapses between injury and the onset of symptoms. Then the question arises whether such an arthritis, manifesting itself after a period of quiescence following an accident, is truly traumatic in origin. According to Bick⁶ a direct blow to an elbow for instance rarely causes immediate damage to cartilage but may disrupt periarticular vessels and produce a vascular disturbance, the cause of later intra-articular changes. Certain criteria for

the diagnosis of traumatic arthritis should control "the well meant but prejudiced testimony of the claimant's physician, as well as the doubts of the impartial or defender's examiner" Bick's criteria follow (1) one should know whether articular function was normal before injury, if the joint was previously affected one must know the degree of previous disability, (2) a diagnosis of traumatic arthritis is not justified in the presence of normal joint function—full painless motion, (3) the presence of pain alone is not enough to justify the diagnosis of intra-articular disease, periauticular disease may account for it, and (4) muscle spasm and definite limitations of motion are generally present Variations from normal range of motion, the presence of any motion not characteristic of a joint, or variations of resistance at the extremes of motion are ipso facto evidence of disease

Not all patients without roentgenographic alterations are malingerers Intra-articular disease may be absent or insufficient in amount to produce them, but periauticular disease (such as rupture of a supraspinatus muscle) may be present In the absence of roentgen-ray alterations diagnosis rests on clinical findings swelling, tenderness, painful limited motion

A "temporo-mandibular joint syndrome," described by Costen^{7,8,9} may arise from mal-occlusion of natural or artificial teeth or in edentulous mouths Mandibular joint destruction may result from lack of molar teeth or badly fitting dental plates permitting overbite articular destruction may be unilateral from one-sided, poor molar support Symptoms are variable and include constant or intermittent catarrhal deafness, "stuffiness" of ears, tinnitus, snapping noises in ears while chewing, dull pain in and about ears with or without herpes of the external canal and buccal mucosa, dizziness (generally mild, sometimes severe), severe constant headaches which may be vertical, occipital or postauricular and which persist after "sinusitis" is treated, glossodynia or burning pain in the throat or side of nose, and tenderness over mandibular joints Symptoms may be promptly relieved by inflating eustachian tubes or interposing disks between the jaws Roentgenograms may show erosion of heads of condyles and articular eminences Symptoms are produced by erosion of the bone of the glenoid or mandibular fossa, impaction of condyles against the thin bone separating them from the dura and its rich nerve supply, irritation of the auriculotemporal nerve, reflex pain and sensory disturbances in the chorda tympani nerve Treatment consists of repositioning the jaws by proper dentures which move condyles away from the range of the chorda tympani and auriculotemporal nerves

(No description of the micropathology of joints was given—Ed)

Articular Disease Aggravated by Trauma If an injured patient is found to have had previous symptoms in other joints, a mild atrophic arthritis may be present (Bick⁶) The assessment of disability is difficult for patients who after injury are found to have hypertrophic changes in the

spine, hips or knees These changes may have long antedated the injury and may represent, not traumatic hypertrophic arthritis, but senescent hypertrophic arthritis which is so common in men over 40 years of age and which may be symptomless Such a condition may be aggravated or made symptomatic by injury The effect of injury can be evaluated only by noting the degree of greater functional and roentgenographic abnormality on the injured side than on the opposite side affected only by senescent hypertrophic arthritis

Pathologic and Roentgenographic Alterations According to Bick,⁶ the primary reaction in traumatic arthritis is invariably synovitis, "a congestion of synovial and subsynovial strata" Allison and Ghormley (1931) showed that when cartilage is affected, a degenerative arthritis may be produced fibrillation and degeneration of cartilage Secondary reactions in articular bone may occur, producing roentgenographic changes hypertrophic in nature Roentgenographic alterations in traumatic hypertrophic arthritis therefore may resemble those in senescent hypertrophic (osteo-) arthritis That two such widely different causes (acute trauma on one hand, and presumably a chronic degenerative process of age and wear and tear on the other) may produce similar roentgenographic abnormalities indicated to McMurray¹⁰ that "hypertrophic arthritis" (in the roentgenographic sense) is not one disease but a reaction of articular tissues to several different agents (including gout and gonorrhea—Ed) It must be borne in mind, then, that roentgenographic "hypertrophic arthritis" is not necessarily either traumatic hypertrophic arthritis or senescent hypertrophic (osteo-) arthritis McMurray¹⁰ and Doub¹¹ believed that monarticular hypertrophic arthritis, particularly of a hip, probably represents traumatic hypertrophic arthritis, but bilateral hypertrophic arthritis represents the syndrome of senescent hypertrophic (degenerative, osteo-) arthritis

Doub and Jones¹² were unable to prove that single, severe trauma produced hypertrophic arthritis Thirty patients, aged 12 to 71 years (average 44), suffered fracture of one of the long bones of a leg Eight months after injury there was no evidence of arthritis of adjacent hips or knees in 28 cases In one case moderate hypertrophic arthritis of a knee, present before injury, was not increased In one case of fracture of the upper part of a femur, which united strongly but with a definite varus deformity, slight changes indicating an early arthritis of the adjacent knee resulted It was concluded that chronic trauma was a much more likely factor than single acute trauma in producing hypertrophic arthritis

Synovial Fluid in Traumatic Arthritis Synovial fluid in traumatic arthritis may be characteristically altered increased erythrocyte content and icteric index (Forkner, 1930) The finding of a positive Wassermann reaction on synovial fluid should not necessarily change the diagnosis from traumatic to syphilitic arthritis Bick⁶ reminds us of Osler's dictum "Even a syphilitic may have traumatic arthritis"

Treatment Early vigorous treatment of injured joints may be necessary to prevent chronic disability^{13, 14} This includes rest and the proper type of physical therapy In some cases physical therapy may give great relief, in others (post-traumatic epicondylitis humeri) rest and splints alone may be indicated Physical therapy should not be long continued when no benefits are derived therefrom By treating compensation cases too long physicians may make invalids of them, taking from them the responsibility of getting well and making them rely on somebody else In such cases physical therapy should be given in a hospital by a physician on a fixed salary, independent in his judgment as to when a patient should be discharged Professional physical therapy should be supplemented by home physical therapy

Carruthers¹⁵ reported that early aspiration of synovial exudates in knees was generally followed by early resumption of walking and a good functional restitution He favored avoidance of weight bearing for a week after aspiration, advising the patient to move his joint in bed, and allowing him to walk with crutches Bick⁶ condemned the routine aspiration of such exudates unless they are persistent

By applying a "sponge-compression dressing" Forrester¹⁶ avoided the use of aspiration, casts or splints in cases of traumatic synovitis of knees

A protective cotton pad was placed in the popliteal space and held in place by a circular dressing of sheet wadding A porous rubber bath sponge was cut longitudinally to fit the contour of the synovial cavity This was held in place by a gauze bandage By its gradual expansion as the exudate resorbs, the rubber sponge exerts a constant compression which hastens absorption of the exudate The bandage is reapplied every four or five days The exudate disappears in three to six weeks No edema of the leg occurs and the patient is permitted to walk and work throughout treatment

Histamine iontophoresis was advocated by Kling¹⁷ The use of short wave or high frequency diathermy was favored by Bierman and Schwarzschild¹⁸ Synovectomy¹⁹ and arthroplasty^{20, 21} are occasionally indicated

Stenosing Tendovaginitis at the Radial Styloid Since its first description in 1895 by de Quervain, about 200 cases of this condition have been reported The tendon sheaths of the abductor longus pollicis and extensor pollicis brevis are involved in a marked fibrosis of the common sheath in the groove at the lower end of the lateral surface of the radius Brown²² recorded a typical case, the third report in English The condition is regarded of traumatic origin from excessive use of the thumb as in writing, washing, wringing clothes, chopping wood, and so forth

Brown's patient, a woman aged 62, had a severe constant boring pain in the left wrist at the styloid process Pain invaded the arm and was aggravated by motion of the wrist, especially of the thumb Local swelling and tenderness were present Although roentgenograms are usually negative, periostitis was present De Quervain's operation is generally advocated for such conditions incising the tendon sheath under local anesthesia Operation being refused in this case, a plaster

cast was applied to the wrist and thumb, the latter in full abduction and extension. After 18 weeks the patient was cured. (It is regretted that the diagnosis of stenosing tendovaginitis rather than local periostitis could not have been verified by operation—Ed.)

GONORRHEAL ARTHRITIS AND TENOSYNOVITIS

Clinical Data The clinical features of gonorrhea of articular and periarticular tissues have again been reported^{23, 24, 25}. To his previous series of 69 cases presented with Keefer,² Myers has added 16 more, reported with Gwynn.²⁵ Several points are worthy of reemphasis. Gonorrheal arthritis generally appears within 10 to 21 days after the initial urethral infection, but occasionally may not appear for months or years thereafter. An acute polyarthritis or polyarthralgia was present in 87 per cent of the cases of Myers and Gwynn. An initial polyarthralgia may resolve into a more stubborn monoarthritis. A monoarthritis alone was present in only 13 per cent of the cases. This is contrary to previous teaching. Knees, ankles, wrists, metacarpophalangeal joints and shoulders are most frequently affected. Fever (to 104° F) and leukocytosis (to 23,000 leukocytes) are generally present. The sedimentation rate was increased in all of Myers and Gwynn's cases. Certain misconceptions have been that gonorrhea affects the os calcis with spur formation so often that most cases of calcaneal spurs should be considered gonorrheal, and that involvement of the spine, temporo-mandibular or sternoclavicular joints is common. Current reports again refute these ideas. Gonorrheal spondylitis is uncommon. Of Woods' ²³ 70 patients with gonorrheal arthritis, only one had spondylitis. Involvement of a sternoclavicular joint is "unusual"²³, only two of 85 patients had it.²⁵ Gonorrheal spurs are rare—seven instances in 85 cases. These observations confirm Von Lackum's contention (1930) that "gonorrheal spurs" is a misnomer.

Gonorrhea tends to affect tendon sheaths. Tenosynovitis with arthritis is common. Extensor tendon sheaths of palm and wrist are most commonly affected. Of Myers and Gwynn's ²⁵ patients with gonorrheal arthritis, 48 per cent had tenosynovitis. It occurs without arthritis much less commonly. The incidence of purulent tenosynovitis is reputedly rare—1 in 7,000 cases of gonorrhea in males. Four new cases were reported by Murray and Morgan,²⁶ Zadek,²⁷ and Birnbaum and Callander.²⁸ The last named reviewed the literature. The tenosynovitis may be acute or chronic. Although severely affected, the tendons are rarely destroyed. Mild subacute trauma precipitated, and conditioned the location of, the attacks in three of the four new cases reported. Involved areas were the long head of the biceps brachii at the left shoulder, the radial and ulnar bursae at a wrist, and the tendons of a right thumb and those of an index finger. Gonococci were found in smears of pus from two of three cases examined. In Zadek's case, smears and cultures from pus were negative for gonococci, but microscopic examination of the tendon sheaths showed numerous pus cells with intracellular, gram-negative, biscuit-shaped diplococci.

(The patient denied genital gonorrhea. A purulent vaginal discharge was present but smears revealed no gonococci. Gonococcal complement fixation test was negative on the third day of the tenosynovitis. Regardless of these facts the report and photograph seem to warrant acceptance of the diagnosis made—Ed.)

Surgical drainage was performed in these cases. Functional restitution was generally good.

Complications In 20 per cent of Myers and Gwynn's cases²⁵ a catarrhal conjunctivitis was present. Non-purulent in type, it lasted about two weeks. No gonococci were recovered from the scanty mucoid exudate. Iritis was present in 3.5 per cent, ulcerative aortic endocarditis in 2.4 per cent. Woods²³ occasionally noted lymphangitis.

Roentgenograms Some have asserted that roentgenographic alterations in gonorrheal arthritis are at times highly characteristic if not pathognomonic. Ankylosis between patella and femur, "moth eaten vacuolated areas of decalcification," and "spotty ground-glass atrophy" of juxta-articular bone have been offered as characteristic alterations. The majority opinion has been that such alterations simulated those of other arthritides and were not specific. This was the conclusion of Kapo²⁴ and of Ferguson, Kasabach and Taylor²⁰. A great variety of nonspecific alterations, from simple soft-tissue swelling to diffuse bony ankylosis, was encountered, as should be expected in a disease of such diverse manifestations and variable severity. A clinical diagnosis cannot be ventured by a roentgenologist unless he knows the approximate duration of an arthritis and whether the part has been used. In some cases of acute gonorrheal arthritis of short duration, roentgenograms may resemble those of old tuberculous arthritis. If one is familiar with the time elements in a given case, when a roentgenogram exhibits destructive changes simulating tuberculous arthritis which are known to have developed rapidly (within a few weeks—much faster than is usual in tuberculous arthritis)—such a roentgenogram should arouse suspicions of gonorrhea. Diagnosis must be confirmed by clinical data.

Laboratory Data Diagnosis and proper treatment of gonorrheal arthritis depend of course on proof that the patient has gonorrhea. It is imperative that physicians be familiar with certain special knowledge: the rather individualized technic of obtaining an honest history, the physical signs to search for and the best method of examination, and the relative significance and reliability of clinical and laboratory data. These matters are reviewed in further papers³⁰ of the Neisserian Medical Society of Massachusetts.

Isolation of Gonococci Isolation and identification of gonococci from smears are less accurate than by the new culture method which utilizes "the oxydase reaction" with tetramethylparaphenylenediamine hydrochloride, bacterial growth being enhanced by an atmosphere of CO₂. First described by Gordan and McLeod (1928), the method was modified and extended by McLeod and his associates (1929, 1934). Its value was confirmed by Price (1929) and by Leahy and Carpenter³¹. Thompson³² simplified the

manner of applying CO₂. By this method gonococci were isolated by McLeod et al (1934)² twice as often as from smears

(One of us noted the comparable recovery of gonococci by the two methods as done by Thompson. From 175 patients suspected of having gonorrhea, cultures or smears were "positive" in 44 [25 per cent]. In 14 of these 44 cases both cultures and smears were positive, in 30 cases smears were negative but cultures were positive. Cultures have been of great help in confirming suspicions of gonorrheal arthritis.—Ed.)

When synovial exudates were present, gonococci were recovered by Myers and Gwynn²⁵ from 25 per cent of the exudates. Kinsella³³ found it extremely difficult to recover gonococci from synovial fluid in cases with a copious, thin straw-colored effusion, but found them with comparative ease both in smears and on culture in cases presenting a dense, brawny, exquisitely tender periarticular infiltration and relatively scanty purulent synovial fluid.

Gonococcal Complement-Fixation Reaction This test on blood is gaining recognition as one of considerable value, one that should become a routine diagnostic procedure^{29, 34}. King³⁵ feels it is as useful in gonorrhea as the Wassermann reaction in syphilis. Myers and Gwynn²⁵ found it positive in 86 per cent of 43 cases of proved gonorrheal arthritis. McEwen, Bunim and Alexander²⁹ obtained a positive reaction in 98 per cent of 43 cases. Certain errors in technic and in the interpretation of the test must be avoided. By using a new antigen and a new technic, Price³⁶ thought the test had been made more dependable and cross-fixation reactions had been excluded. By testing complement both for its hemolytic and fixing powers, irregularities can be avoided, according to Thomson, Hamann and Park.³⁷

The reaction is usually negative, rarely positive the first 10 days, and generally becomes positive between the second and third week of infection. A negative reaction may sometimes be obtained if a urethral infection is "open" such a negative test indicates efficient drainage with insufficient absorption of substances to produce the reaction in blood. In such cases a negative test can and does occur even when smears are positive (King³⁵). A negative test should also be expected when a patient with gonorrhea is really cured or in non-gonorrheal cases. A weakly-positive reaction should not be considered certain evidence of infection, but if it is repeatedly (weakly?—Ed.) positive or strongly-positive Price³⁶ concludes that the patient has gonorrhea. Repeated tests are recommended and will prevent diagnostic errors. Tests should always be interpreted in the light of clinical findings. Special caution must be taken to avoid errors in diagnosis when a patient with old or recent gonorrheal urethritis later develops a (coincident) non-gonorrheal arthritis. A positive complement fixation reaction may be present but is unrelated to the arthritis^{23, 29}.

Skin Reactions to Gonococcus Filtrate When Cumming and Bur-

hans³⁸ gave intradermal injections of gonococcus filtrate (Corbus-Ferry) in the treatment of gonorrhea, the urethral discharge at times increased, as it may with nonspecific protein injections. Local skin reactions at the site of injection included an area of redness surrounding a wheal. Injections of 0.1 to 0.4 c.c. of the filtrate into non-gonorrheal controls produced no skin reaction and no urethral discharge. Cumming and Burhans concluded that both the provocative effect on the discharge and particularly the skin reaction are useful in diagnosis. They thought that the skin reaction was specific because injections of bouillon used in preparation of the filtrate produced no reactions in gonorrheal or other patients.

(The report presents but few details of the reaction. "Several" controls were used. Further information should be forthcoming before one can evaluate the procedure.—Ed.)

Differential Diagnosis When, as often happens, gonorrheal arthritis begins as an acute polyarthritis or polyarthralgia, shifting rapidly from joint to joint before localizing (if ever) more stubbornly in one joint, its differentiation from rheumatic fever may be difficult as two of Myers' cases illustrate.³⁹

A young woman developed acute febrile polyarthritis. Aside from her joints, physical examination was negative. A diagnosis of rheumatic fever was entertained, but salicylates persistently failed to give relief and electrocardiograms were repeatedly normal. Dissatisfied with a diagnosis of rheumatic fever, Myers examined synovial exudate. Gonococci in pure culture were found. The synovial leukocyte count was 58,900 (90 per cent being polymorphonuclear cells). The gonococcal complement fixation test was positive on blood and on synovial fluid. Uterine cervical secretions revealed no gonococci.

A young man developed an acute, febrile migratory polyarthritis five days after an upper respiratory tract infection. The heart was not enlarged. An apical systolic murmur was present, transmitted to the axilla. The second pulmonic sound was accentuated. He had had gonorrhea four and seven years previously and prostatic secretions now contained gonococci. Gonorrheal polyarthritis was considered, but the electrocardiogram revealed partial heart block, a PR-interval of 0.24 second. Aspirated synovial fluid contained 10,450 leukocytes per cu. mm., 88 per cent being polymorphonuclear cells. No gonococci were found in the synovial fluid and the gonococcal complement fixation test was doubtfully positive thereon and on blood. When salicylates were given the fever and arthritis subsided but returned when salicylates were omitted. A presystolic murmur developed. Final diagnosis was rheumatic fever, with rheumatic polyarthritis and carditis and an incidental prostatic gonorrhea.

In the differentiation of gonorrheal polyarthritis and rheumatic fever, these points are important. The value of the complement fixation test and diagnostic aspiration of synovial fluid is evident but results must be carefully interpreted. Prodromal pharyngitis commonly initiates rheumatic fever but is not infrequently seen with gonorrheal arthritis (10 per cent of Myers' 69 cases). Electrocardiographic alterations speak for rheumatic fever, as do response to salicylates and associated involvement of pleura or

lungs The presence of serous conjunctivitis suggests gonorrhea (it was present in 20 per cent of Myers' cases)

Treatment Further experience indicates that fever therapy may be the method of choice For patients for whom fever therapy is not available or is contraindicated other methods must be used Garland's experience⁴⁰ with roentgen therapy in 30 cases of gonorrheal arthritis led him to believe it may be equal or superior to fever therapy Roentgen therapy is much simpler than fever therapy, which he considers an exhausting "ordeal by fire" Affected joints were given small doses of roentgen-rays twice weekly for two to three weeks Some patients had previously had foreign protein therapy without relief Twenty-eight patients (93 per cent) were much improved, two (7 per cent) were unimproved A total of 80 joints were affected 30 became symptom free, 45 were "improved," five were unimproved About 50 per cent of the improved cases appeared to be completely cured within a few weeks after treatment (This apparently refers to articular lesions no comments on the primary infection were made) The remainder improved gradually, became free of pain but had slight articular stiffness or disability Five patients, certain of whose joints were left untreated as controls, showed no improvement in untreated joints Garland cited the similar experiences of Akerlund (1930) and of Westermarck (1933) the former regarded the effect of roentgen therapy in gonorrheal arthritis as "magical," the latter as better than any other method for gonorrheal hips

(Garland's report is arresting both because of, and in spite of, its optimism The matter of controls might seem to have been satisfied by the continuation of disease in untreated joints, but this is not full proof Garland realized that gonorrheal arthritis is an extremely "labile" form of arthritis, often capable of being rapidly relieved by various remedies or spontaneously by the self-limiting nature of the disease His comment that in some of the acute cases the relief of pain was "almost theatrical" makes us believe that a transitory arthralgia, not a true arthritis, must have been frequently present No adequate explanation of the relief is offered, no cultural examination of joints was made, no study of the effects of roentgen-rays on the gonococcus in vitro or in vivo It is to be regretted that results in this series were not compared with a control series of patients whose joints were treated otherwise, or were untreated—Ed)

Three patients "were benefited" with histamine iontophoresis (Kling¹⁷) Cases of gonorrheal arthritis were among the arthritides that responded favorably to gold salts (Forestier,⁴¹ Slot⁴²)

(In these reports few or no details concerning the joints are given, the number of patients treated is quite small and no control series treated by other than the favored remedy is presented—Ed)

Gonococcal immunogens, sterile milk, lactalbumin and the intradermal use of stock gonococcal vaccines are valueless according to Cumming and Burhans³⁸, but the use of gonococcus filtrate (Corbus-Ferry) seemed to give "specific aid" in the treatment of 124 patients with gonorrhea and its

complications, including arthritis. This filtrate is a soluble toxin and is not to be confused with vaccines (bacterial suspensions), immunogens (bacterial washings), toxoids (solution of formaldehyde detoxified toxin) or serums (antitoxins). Patients generally received 7 to 10 injections, sometimes as the sole treatment, usually as an "adjunct to mild local treatment."

(Results were not statistically presented, no controls were mentioned. Hence evaluation thereof is not possible—Ed.)

Wolbarst⁴³ considered gonorrheal arthritis usually secondary to a primary focus in the vesicles for which vasotomy, with the injection of 5 per cent argyrol, is the most effective treatment. In such cases Goldstein,⁴⁴ however, opened the vesicles and drained them by perineal exposure. When aspiration of joints revealed serous or serofibrinous synovial exudate, Cooperman¹⁹ used "closed drainage" (aspiration and irrigation). When thick turbid exudate was recovered, "open drainage" by incision was necessary to prevent serious articular destruction. (Some of us believe that even in such cases conservative treatment, aspiration and rest, or fever therapy, is effective—Ed.) By one or the other method Wolbarst⁴³ treated 136 gonorrheal joints of 43 infants, to all but 11 joints complete functional restitution was provided. After ankylosis has occurred much can still be done by arthroplasty^{20, 21}. To prevent articular and other complications, in view of the local influence of trauma, Woods²³ advised patients with acute gonorrhea to live a sheltered life, preferably in bed temporarily.

Fever Therapy. Sixteen more reports on fever therapy for gonorrheal arthritis have appeared since those mentioned in our last Review (Warren, Carpenter, Boak⁴⁰, Kendell, Webb, Simpson^{45, 46}, Tenney⁴⁵, Atsatt and Patterson^{45, 47}, Hench, Slocumb and Popp^{45, 48, 49}, Bierman, Horowitz^{45, 50}, Stecker⁴⁵, Hefke^{40, 51}, Arnold⁴⁵, Lepore⁴⁵, Schnable and Fetter^{45, 52}, Strickler^{45, 53}, Short and Bauer⁵⁴, Wolf⁵⁵). (One of us has published summaries of the literature on this subject to date [Hench^{29, 48, 56}—Ed.]) Current reports apparently confirm the excellent results noted earlier. It would appear that fever therapy acts almost as a "specific" in the majority of cases of gonorrhea and its complications. Some regard the development of fever therapy for gonorrheal arthritis as the greatest advance of the decade in the field of articular diseases. Therefore, a brief tabular synopsis of reports published from 1932 to 1935, inclusive, seems worthy of presentation (table 1).

Boak, Carpenter and Warren⁴⁵ showed that the thermal death time of 130 strains of gonococci in vitro at 106° to 107° F. was about 6 to 27 hours. A patient may be infected with more than one strain. Strains derived from a patient and from his consort generally have the same thermal death time. When a patient exhibits strains whose thermal death times differ markedly, he is probably affected with both an old and new infection. Articular strains are somewhat less resistant to heat than urethral strains, therefore, gonorrheal arthritis may subside before an associated urethritis does.

TABLE I
Results of Fever Therapy for Gonorrheal Arthritis (1932 to 1935)

Authors	Method used	Dose of fever		Treatments		Number patients treated	Results per cent				Comments
		Hours each treatment	Temperature (Fahrenheit)	Days interval	Total number		"Cured," Symptom-free	Marked relief	Mod-erate relief	Little or no relief	
Carpenter and Warren (1932)	Diathermy and radiothermy	5-7	106.7	*	1-2	*	*	*	*	*	"Gonorrheal arthritis usually cured"
Bishop Horton and Warren (1932)	Diathermy and heated cabinet	5	106.7-107 (rectal)	*	2	9	*	*	*	*	Results very encouraging joints become painless
Warren and Wilson (1932)	*	5	106.7 (rectal)	*	1-2	2	100				
Warren, Carpenter, and Boak (1935) ⁴⁵	*	5-17	106.7 (rectal)	*	1 (equal to thermal death time of patients strain)	15	87	*	*	*	"Patient may be infected with two strains. The thermal death time of that of patient and consort generally about the same. Strains from urethra and joints may have different thermal death times, usually a little shorter from joints"
Tenney (1932)	Radiothermy	3-4	101-106 (rectal)	*	*	*	*	*	*	*	"Acts almost as a specific"
Tenney (1935) ⁴⁵	*	*	*	*	*	3	100				
Berris (1933)	Heated cabinet	2-4	102-103	*	1-6	2	50			50	
Simpson Kiebig, and Sittler (1933)	Radiothermy and heated cabinet	5	105-106 (rectal)	*	*	*	*	*	*	*	"Results gratifying"
Simpson (1934)	Radiothermy and heated cabinet	5	105-106.8 (rectal)	7	*	12	100				"Results uniformly successful in acute cases"
Kendall Webb and Simpson (1935) ⁴⁶	Kettering hypertherm	6-7	106-107	3-5	1-5	Acute 19 Chronic 12	84 11	*	*	*	

TABLE I—Continued

Authors	Method used	Dosage of fever		Treatments		Number patients treated	Results per cent				Comments
		Hours each treatment	Temperature (Fahrenheit)	Days interval	Total number		Cured Symptom free	Marked relief	Mod-erate relief	Little or no relief

When estimations of the thermal death time are possible, applications of a single session of fever, of a number of hours equal to the thermal death time (generally 5 to 17) at 106° to 107° F, were advocated recently by Warren, Carpenter and Boak⁴⁰ Prompt cure was practically always obtained for those so treated Good results were also obtained, however, when a period of fever of three-fourths to half the thermal death time was given, suggesting the assistance of defense factors in the body Since routine estimation of the thermal death time of a patient's strain is not yet practicable, most physicians favor a number of short sessions (as table 1 shows) rather than one long session, but sessions should be given not less than twice a week or strains may become heat resistant

Various methods for producing artificial fever have included general diathermy, general (as contrasted with local) radiothermy, heated air-conditioned cabinets, hot baths and heated air currents An analysis of results does not suggest that one is superior to another so far as they affect the disease A choice of method resolves itself into selection of that one which is most comfortable, least dangerous and least expensive to the patient The majority favor the administration of 5 to 6 hours at 106° to 106.8° F (rectal) as one session Treatments are given every 3 to 5 days Two to five or six fever sessions are necessary, generally fewer for acute than for chronic gonorrheal arthritis Statistical data permitted the percentage evaluation of published results in a total of 182 cases of acute and chronic gonorrheal arthritis Of these 182 patients, 70 per cent (128) were more or less promptly "cured," becoming symptom-free About 15 per cent more were markedly relieved, about 10 per cent were moderately relieved, and 5 per cent received little or no benefit Results were definitely better in acute than in chronic cases (over 6 weeks' duration) Of a total of 33 patients with chronic gonorrheal arthritis, about 30 per cent were "cured," about 45 per cent markedly relieved, 15 per cent were only moderately relieved and about 10 per cent were not benefited Considering the remaining 149 patients to have had acute arthritis, about 75 per cent were "cured," 10 per cent markedly relieved, 10 per cent only moderately relieved and 5 per cent unrelieved If one chooses to consider as acute only the 66 specifically labelled as "acute cases," the results were still most gratifying and were about the same 70 per cent were cured, 15 per cent markedly relieved

Of the approximately 30 reports to date only one is at variance with the others In Strickler's experience^{45, 53} results in 13 cases were no better than with other treatments, nevertheless in his 9 acute cases, 6 patients were cured or markedly relieved Short and Bauer⁵⁴ obtained "excellent results" with artificial (diathermy) fever but obtained equally good results with fever induced by typhoid vaccine intravenously

(Culver in 1919 noted marked improvement in 22 of 24 patients with gonorrhea treated by fever from intravenous injections of killed colon bacilli, meningococci or gonococci—Ed)

These experiences indicate that in cases of gonorrheal arthritis some form of fever therapy should, when possible, be instituted early, but the method used must be able to provide a controllable fever sufficient to reach or exceed the thermal death time of the gonococcus. In cases in which gonorrhea is strongly suspected but cannot be proved, the patient should always be given the benefit of the doubt and be subjected to a couple of trial sessions of fever. If his response is marked, gonorrhea probably was present. Patients who have had arthritis more than six weeks have lost valuable time, but even in chronic cases results may be quite good. However, fever therapy should be regarded as a fire-brigade, not a corps of carpenters, it may extinguish the flames of gonorrhea but will not restore the architecture of the joint. Therefore, when a process is almost burned out except for residual stiffness, fever therapy is not indicated. In two cases of chronic gonorrheal arthritis seen by Kendell, Webb and Simpson,⁴⁶ marked stiffness remained after fever therapy alone, but this was relieved by orthopedic manipulation under anesthesia immediately followed by a fever session.

Gonorrhea of the female pelvis is more difficult to cure than this same infection in males. In such cases the combined use of fever therapy and Elliott treatments or pelvic diathermy may be more effective than fever therapy alone (Simpson⁴⁵). Bierman and Horowitz^{45, 50} strongly favored the supplemental use of vaginal diathermy electrodes as productive of more local heat than Elliott treatments. Treated by a general temperature of 105° F by fever cabinet and a vaginal temperature of (not more than) 110° to 111° F by vaginal diathermy, 37 of 41 patients became bacteriologically "negative" after one to three sessions.

Criteria of Cure The patient considers his joints cured when symptoms leave, the patient himself is not well until the original focus is also cured. Of 29 patients treated by Desjardins, Stuhler and Popp,⁵⁷ 25 were cured after one to 10 fever sessions, "cure" meaning complete disappearance of urethral discharge, symptoms and gonococci in spite of repeated smears and culture, patients remaining free of symptoms for several months. Discharges ceased and smears became "negative" in 9 cases after one fever session, in four cases after two sessions, in three cases after three sessions, in two cases after four sessions and in four cases after five sessions. Three were cured only after seven, eight and ten sessions. King's³⁵ criteria of cure were essentially similar although he relied considerably on the complement fixation test. In cases wherein treatment was by gonococcus vaccine the test became negative six weeks after patients were clinically cured. However, a negative test is less reliable than a positive test. King believed that when a patient not treated with gonococcus vaccine still presents a positive test even in the absence of symptoms, a persistent focus of infection is undoubtedly present.

(None of these reports included control series of patients treated other than by fever. It cannot be doubted that results from fever are excellent, but fever therapy is a strenuous, expensive, and difficult form of therapy to apply, one which probably

should not become routine in all cases. There are certain dangers in and contraindications to fever therapy. One must remember that articular gonorrhea disappears rapidly and spontaneously in many cases, particularly if "arthralgia" and not true arthritis is present. Even so, under older methods of treatment many cases responded satisfactorily without residue, generally those with serous and not purulent synovial exudate with involvement mainly in subsynovial rather than synovial tissues,—cases in which the synovial cavity was probably not actually invaded by gonococci (Myers, 1934). Statistics on end-results of older methods are, curiously, difficult to find. Only a few are cited in Mondor's extensive monograph⁵⁸. Complete restitution of articular function was obtained in 50 per cent of Rasch's cases (1916), in 61 per cent of Schussler's cases (1912). Others noted serious sequelae and articular impotence in at least 30 to 50 per cent of cases (Charrin, 1914). In only 30 per cent of Kong's and in only 14 per cent of Bodganow's cases (1904), were joints completely cured. Results by older methods depended, of course, on the degree of articular involvement—whether purulent arthritis, or merely a toxic arthralgia or non-purulent arthritis, was present. Further data on how many cases of each type become healed spontaneously, and how many with treatment recover with or without residue are needed as controls to fever therapy. A more rigid evaluation of fever therapy would be obtained by selecting for treatment only those with positive synovial cultures. However, faced with a method which seems to insure the prevention of complications and a rapid (if strenuous) cure in the great majority of cases of urethral gonorrhea, and early restitution of function in those with arthritis, the matter of selection becomes difficult, and one hesitates to set up controls treated by methods which now seem outmoded. Results in cases of patients so treated, patients unable to afford fever therapy or for whom it is contraindicated, should be carefully compared to those herein tabulated—(Ed.)

General Remarks on Fever Therapy Fever therapy should not be given in a physician's office. It can be safely administered only in a hospital equipped with specially trained personnel. However, hospitalization after each fever session is generally unnecessary. Physiologic studies have shown that the amounts of fever usually prescribed generally do not harm patients. Hundreds of patients with a variety of diseases have now been so treated. In one series of 400 patients no untoward reactions occurred (Simpson⁴⁵). However, an occasional serious and even fatal reaction is probably inevitable. Only a very few deaths from uncontrolled hyperpyrexia have been reported, four occurred recently of whom two were patients being treated for gonorrhea, one of whom had gonorrheal arthritis^{45, 59, 60}. The great majority of patients tolerate the fever quite well but, to prevent such mishaps, physicians and technicians must be familiar with the physiologic reactions to fever therapy, contraindications, management of patients during sessions, and signs of impending trouble as discussed in the references already mentioned. Interesting also are the following references on physiologic reactions to fever therapy^{45, 61, 62, 63, 64, 65}, on immunologic reactions^{66, 67}, on various methods used for the production of fever^{68, 69, 70}, and on its clinical application and the management of patients^{71, 72, 73, 74, 75, 76}.

Short-Wave Therapy This should not be confused with "fever therapy". In the early development of fever therapy short waves were used to produce the fever by "general radiothermy" or "general short-wave dia-

thermy" Patients received a general, not a local application of the waves Now, short wave currents are being used to produce merely a local heating or other local effect, not a general fever In this newer utilization of short waves only local parts, such as joints, are exposed to the waves

The method is variously called "short-wave" (or "ultra short wave") therapy or "short wave high-frequency" (Schliephake) or "short wave diathermy" (Nagelschmidt), "radiothermy" (Bierman) or "radiathermy" (Kobak) Ordinary or "long-wave" diathermy concerns a wave length of 100 to 400 meters (a current frequency of $\frac{1}{4}$ to 3 million cycles per second) "Short wave diathermy" (the term approved by the Council on Physical Therapy of the American Medical Association) concerns a wave length of 12 to 30 meters (10 to 25 million cycles per second) "Ultra-short wave diathermy" concerns a wave length of 3 to 12 meters (up to 100 million cycles per second) With ordinary diathermy, heat is produced by conduction, with short wave diathermy heating is due to dielectric losses in a condenser field⁷⁷

Patients with gonorrheal arthritis were benefited by short wave currents, according to Bierman and Schwarzschild,¹⁸ Kling,⁷⁸ Torbett,⁷⁹ and Kobak⁸⁰ Kling found reports of 25 patients so treated, with "improvement" in 23 Two of his own patients treated by a 23 meter wave machine also "improved" Of six patients treated by Torbett, 3 obtained "good improvement", 3 were "moderately improved" One of Kobak's patients with a gonorrheal wrist obtained marked relief from three treatments

(No details were given in any of these cases—Ed)

Several special claims are made for short wave therapy, among them greater and more uniform penetration of heat into the body With ordinary diathermy superficial tissues are heated more than deep tissues, with short wave currents this thermal gradient is presumably obliterated or reversed Some have been unable to demonstrate any greater or more uniform penetration of heat than with conventional diathermy^{81, 82} Others, inserting thermocouples into joints and other tissues of animals, observed greater internal (intra-articular) than surface temperatures⁸³ Other claims include a specific bactericidal action Foreign researches suggested that ultra high frequency currents have a lethal action on bacteria, not from a heating effect but because of the peculiarities of the frequency itself By a process called "point-heating" the temperature of microorganisms is presumably raised above their thermal death point without a corresponding elevation in the temperature of the medium^{84, 85} It is claimed that different bacteria are killed by different wave lengths These claims are contradicted, however, by several^{81, 86, 87, 88} Gonococci and other bacteria were unaffected by the various wave lengths used and "heatless bacteriolysis" was not noted

Before short-wave and ultra short-wave diathermy machines are used extensively, their construction must be improved, fire hazards lessened, and more data on their physiologic effects amassed⁷⁷ Using 14 different machines with varying wave lengths from 6 to 25 meters, Mortimer and Beard⁸² found no advantage of any one wave length over another for heating purposes

TUBERCULOUS ARTHRITIS

Clinical Data Among 12,386 admissions to one tuberculosis hospital were 500 patients with tuberculous arthritis, an incidence of 4 per cent⁸⁹ Joint tuberculosis rarely begins in the capsule Extension to joints occurs from an adjacent bone lesion Extension from small bones of the wrists or feet is rapid, that from large bones to adjacent joints may be very slow Weight-bearing joints are involved much oftener than others Joints of legs are affected about three times as often as those of arms (Meng and Chen⁹⁰) Of 224 affected joints in Cleveland's cases,⁸⁹ 95 per cent were in weight-bearing regions (spine included), only 5 per cent were of upper extremities In this series the order of involvement was spine, 49 per cent (especially seventh to twelfth thoracic), knees, 20 per cent, hips, 11 per cent, sacroiliacs, 7 per cent, tarsus, 6 per cent, ankles, 2 per cent, elbows, 2 per cent, wrists, 2 per cent, and shoulders or symphysis pubis, less than 1 per cent Tuberculosis of the sacroiliacs is particularly serious (Cleveland⁸⁹) It must be remembered that polyarticular tuberculosis is not uncommon An ankle, knee, elbow and the spine were affected in a case of Slocumb and Ghormley's⁹¹ Of 100 patients seen by Meng and Chen, 16 had two, four had three, and one had four regions affected Pulmonary tuberculosis has been reported present in from 6 to 65 per cent of cases of tuberculous arthritis In the series of Meng and Chen, 47 per cent had pulmonary tuberculosis, an additional 31 per cent had hilar tuberculosis Of Petter's⁹² 45 patients with tuberculosis of a knee, 82 per cent had tuberculosis elsewhere (55 per cent in the lungs) Tuberculous arthritis occasionally first appears after the age of 50 years Duncan⁹³ reported two cases in men, aged 67 and 68 years, respectively

Tuberculous cysts of the knee joint are rare Elliott⁹⁴ reported two cases with multiple cysts proved tuberculous at operation, roentgenographically they were indistinguishable from osteitis fibrosa cystica In a case of bilateral subdeltoid tuberculous bursitis, Deacon and Ghormley⁹⁵ excised bursae filled with rice bodies weighing 100 and 400 gm Preoperative palpation revealed a peculiar leathery crepitus considered of diagnostic importance

Roentgenograms "There exists no roentgen picture entirely typical of tuberculosis in any of its stages" (Sundt, 1931) To this remark Elliott⁹⁴ and Doub¹¹ agreed Minor variations previously reported² as being suggestive of tuberculosis were again noted by Doub Different roentgenographic aspects of tuberculosis of the knees were diagrammatically presented by Petter⁹²

Treatment The patient, not just his joint, is tuberculous and the patient's primary disease must be energetically treated Even at rest, patients may develop bacillemia with new articular and other foci⁹² The use of gold salts is "not quite so successful" in tuberculous arthritis as in tuberculous rheumatism, according to Forestier⁴¹ (No details were given—Ed)

The intra-articular temperature of a tuberculous joint can be elevated to 105° F by submersion baths⁹⁶ Fever therapy, however, is apparently of no value and may actually harm tuberculous patients Like physical exercise, fever therapy stimulates metabolism—an effect harmful in tuberculosis A few patients with tuberculous arthritis were treated and obtained no improvement therefrom (Duncan and Mariette,¹⁵ Hubei¹⁷) Temperatures available in fever therapy do not affect bovine or avian strains, and have no bactericidal but may have a bacteriostatic effect on human strains of *Mycobacterium tuberculosis* A patient with a tuberculous hip was unrelieved by short wave therapy⁷⁹

Results of conventional surgical treatment were reported^{15, 89, 97} When ankles were affected by abscesses and sinuses Cleveland⁸⁹ advised amputation He condemned resection of knee joints in childhood since it eventually produces considerable shortening of the leg The value of the usual orthopedic measures (resection, arthrodesis, osteotomy) has been questioned by Erlacher⁹⁸ Ankylosis is taken for granted as the ideal result Yet these common practices take years to complete, the tuberculous focus remains and recovery of normal joint function practically never occurs A purely synovial tuberculosis should be treated by synovectomy before articular bone becomes involved According to Erlacher, an improved roentgenographic technic indicates that a tuberculous focus in bone almost always begins as a small, isolated circumscribed focus in the capsule or in the region of a joint but not involving it Early eradication of this focus (by radical extirpation) should be attempted even though rupture into the joint threatens “The advantage of complete cure at one stroke is so great that one may with confidence assume the risks inevitably involved” Such a procedure is possible, according to Erlacher, in about 25 to 30 per cent of cases, and gives results obtainable by no other method It allows rapid, firm healing, decreases the duration of treatment a quarter to half, and in many cases preserves normal motion

TUBERCULOUS RHEUMATISM

Poncet in 1897 described “rhumatisme tuberculeux” as a condition somewhat resembling acute rheumatic fever with pyrexia, pain and swelling of several joints, leading shortly to frank tuberculous arthritis of a single joint Others broadened this concept of the disease and advanced the notion that, in some cases, it resembled atrophic arthritis, in others, hypertrophic arthritis, and in still others, juvenile Still’s disease Some believed it due to an actual tuberculous infection with bacilli in joints The majority, however, have suggested that an atypical tuberculous lesion was present—atypical in that actual tubercle bacilli were absent from joints, the reaction being one of articular allergy to a distant tuberculous focus Just as there has been no agreement as to the clinical picture of tuberculous rheumatism, so there has been no agreement as to its pathologic or roent-

genographic picture. Hence the condition has been accepted by few clinicians outside of France. In France, however, 12 of 16 "rheumatism specialists" interviewed by Slocumb⁹⁹ considered the entity established.

The argument has sharpened since Lowenstein and Reitter (1928) reported that, by a special technic, they could obtain tubercle bacilli in 70 per cent of cultures from blood and synovial fluid of patients who presumably had atrophic arthritis (also from the blood of patients with chorea). Very few have been able to confirm this work (Kallor, 1932) although two French clinicians reported to Slocumb their ability to obtain such positive cultures in 10 per cent of cases of chronic polyarthritis. Criticism of the work of Lowenstein and Reitter was summarized by Tan¹⁰⁰: a difficult procedure is rendered more difficult by the constant change of method, animal inoculations were not used to determine whether the tubercle bacilli recovered in cultures were virulent or not, bacteriologists who learned the method in Lowenstein's laboratory could not obtain the same results elsewhere.

Criteria considered necessary by some for a diagnosis of Poncet's rheumatism were as follows (Kubischky¹⁰¹): (1) the disease under study should be refractory to salicylates, (2) endocarditis should be absent, (3) non-articular tuberculosis should be present, also, (4) a positive tuberculin test, (5) there should be positive animal inoculation from synovial fluid (some would also add, from blood), and (6) there should be a predominance of mononuclear cells in synovial fluid. In this country and in England the entity has been accepted by very few investigators¹⁰² and rejected by the majority^{103, 104}.

Copeman¹⁰² believed that tuberculous foci, at times latent and unsuspected, may be the underlying cause of certain cases now called "rheumatoid arthritis." To support this view two cases were reported.

A 49 year old woman had multiple arthritis of the rheumatoid type following tonsillitis. Her parents had both died of tuberculosis, she had presumably never had it. Sixteen months later, aside from the joints, physical examination, including that of the lungs, was negative. (No roentgenograms of the lungs had been taken as yet—Ed.) Intradermal tests to old tuberculin and to Parke Davis' "protein purified derivative (P P D)" were strongly positive. No focal or general reaction resulted therefrom. The complement fixation test for tuberculosis was positive, but blood cultures sent to Lowenstein's laboratory were negative for tubercle bacilli. An injection of tuberculin was then given for treatment. A notable reaction followed: fever, malaise, increased arthritis. Rales were then heard at the right apex, a roentgenogram showed possible pulmonary tuberculosis. The reaction subsided in a few days. Three months later the patient had a slight cough without sputum.

In the second case a woman, aged 20 years, had chronic monoarthritis of varying intensity in her knee. Two years later the sacroiliacs and the other knee became involved. The next year she was treated (by someone else) for superficial skin ulcers of the legs, presumably tuberculids. Biopsy of the right knee revealed nothing definite for tuberculosis. The next year Copeman found a negative complement fixation test for tubercle bacilli, negative roentgenograms of thorax and knee. The sacroiliacs showed osteitis. Fluid from the knees was negative for tubercle bacilli. Tuberculin tests were positive to both O T and P P D. Five days later one of the old tuberculid scars became indurated, and four days thereafter an acute exacerbation occurred in

the knees and an ankle. A blood culture, sent to Lowenstein, was positive for tubercle bacilli. The general reaction lasted several days.

(These cases are thought-provoking but not convincing. Results of blood cultures would have been more impressive had they been done, not in Lowenstein's, but in Copeman's laboratory, thus confirming the former's technique. It has long been shown that an exacerbation of atrophic arthritis may follow injections of several unrelated substances, such as milk, typhoid and other bacteria as well as tuberculin. There is therefore nothing necessarily specific about the articular reactions to tuberculin which proves them tuberculous. Furthermore, latent tuberculous foci may also be activated by a variety of substances, not just tuberculin [Hench, 1932]. In tuberculosis such reactions to tuberculin are also not necessarily specific.—Ed.)

Regarding the tuberculous nature of Still's disease very dubiously, Moncrieff¹⁰⁴ cited the observation of Grenet (1935) that positive tuberculin reactions were no more numerous in arthritic children than would be expected in a group of healthy children. Were tuberculosis an important causal factor in chronic polyarthritis or atrophic arthritis, the association of the two diseases should be, at least, not uncommon. Yet among 800 of Dawson's¹⁰³ patients with atrophic arthritis only three had (active) tuberculosis. In 4,499 cases of tuberculosis at Saranac Lake, Brown¹⁰⁵ found only 11 cases of atrophic arthritis. Hench¹⁰⁶ restated the conclusion reached by him and Brav (1934) that the existence of tuberculous rheumatism cannot yet be accepted without many reservations.

Although recognizing the insecurity of the entity and the validity of most of the criticism directed against it, Tan¹⁰⁰ cautiously accepted the idea that rheumatism is an allergic disease, a manifestation of articular hypersensitivity to many different bacteria, including tubercle bacilli.

(The few cases presented by Tan as possible examples of "tuberculous rheumatism" seem to us to have been poorly chosen. One patient had for 10 years what we would regard as typical atrophic polyarthritis. Salicylates gave no relief, endocarditis was absent, and residual pleurisy, slight fever, and a positive Pirquet reaction were present. "Animal inoculation" and blood cultures for tubercle bacilli were negative. We cannot therefore see the indications for a diagnosis of tuberculous rheumatism in this case. In another case a patient had pleurisy with effusion and pain and slight swelling of a foot and elbow. Fifteen months later fistulous tuberculosis of the foot developed, tubercle bacilli being found in the discharge and in sputum. The elbow was unchanged. This seems to us like a case of classical tuberculous arthritis, probably of two joints, and not a case of "tuberculous rheumatism." A third patient apparently had had recurrent rheumatic fever and carditis as a child. Some years later milary tuberculosis developed. Tan considered a possible connection between the two diseases, a connection which seems to us very remote. Two typical cases of Pott's disease were also described and the case of a woman who had repeated pain and swelling of a shoulder and elbow. At tonsillectomy tuberculous tonsillitis was found. Such cases as these do not clarify the issue, the ever present likelihood of unrelated coincident or subsequent disease being ignored. They strengthen our opinion that to date the syndrome of tuberculous rheumatism rests on insecure grounds.—Ed.)

Slocumb⁹⁹ found the treatment of "tuberculous rheumatism" in France to be the same as for atrophic arthritis, except that a few physicians were

using small injections of tuberculin Foerster¹¹ used gold salts with reported satisfaction

PNEUMOCOCCAL ARTHRITIS

Pneumococcal arthritis is rare. It generally occurs with pneumococcal pulmonary infection (secondary pneumococcal arthritis). Primary pneumococcal arthritis (without a pulmonary infection) occasionally occurs (as it did in 26 of 185 cases of pneumococcal arthritis collected by Plisson and Biousse, 1920). Occasionally a non-suppurative, but generally a suppurative monoarthritis is present from which pneumococci can be recovered. Even when the infection is purulent articular function is generally restored and ankylosis is rare. A case of the primary type was reported by Bloomberg.¹⁰⁷

A 27 year old negress developed fever and a hot, swollen, tender left big toe. Aspiration of the first metatarsophalangeal joint one week later revealed 5 c.c. of thin flaky fluid and fibrin in which pneumococci, type IV, were found. Washed with mercury bichloride, the joint was symptomless four days later. Six weeks thereafter the left ankle and left wrist became involved. Aspiration of the wrist was not done, aspiration of the ankle revealed 15 c.c. of fluid, culture of which was negative. Repeated blood cultures were negative. Roentgenograms of joints were negative. Further treatment consisted of injections of a vaccine of pneumococci and streptococci. Articular restitution was complete.

(Pathological studies were not done. Such studies were recently reported in one case by Allison and Ghormley [1931]—Ed.)

SYPHILITIC ARTHRITIS AND CHARCOT'S DISEASE OF JOINTS

Syphilis may affect joints directly as a syphilitic synovitis or arthritis, or indirectly as an osteoarthropathy ("Charcot joint") secondary to syphilitic tabes dorsalis. Illustrative of the former, Myers³⁹ presented the case of a boy "probably with congenital syphilis, with recurrent acute arthritis of both knees."

This boy, an orphan aged 15 years, knew nothing about his family history. At the age of 13 both knees became tender, painful, and swollen for one month and recovered fully under rest alone. Two years later they again became swollen, painful, red and tender. Slight fever and adenopathy were present. Roentgenograms of joints were negative. The Wassermann reaction was positive on blood and on synovial fluid, cultures of joint fluid and the guinea-pig test were negative. Adenopathy disappeared and the joints fully recovered during treatment with neoarsphenamine.

(No diagnosis was definitely given but that of congenital syphilis and recurrent acute syphilitic arthritis is inferred to have been given. The diagnosis of congenital syphilis was apparently based on the idea that the boy was too young to have acquired syphilis. However, no stigmas of congenital syphilis were present and the boy may very well have acquired syphilis. The diagnosis of syphilitic arthritis was apparently made on the basis of the positive Wassermann reaction on synovial fluid and the remission in symptoms coincident with antisypilitic treatment. These data seem to us insufficient for the diagnosis. Myers admitted "the presence of positive Wassermann reactions on blood and synovial fluid cannot be considered proof of the etiology of the arthritis." Wassermann reactions on synovial fluid of normal joints tend to follow

those on the blood of syphilitics (Forkner, 1930) Had the reaction been negative on blood but positive on synovial fluid, it might have been more significant as far as joints were concerned (Kling, 1932) A diagnosis of syphilitic arthritis should in part rest on the success of antisyphilitic treatment after other treatment has failed In this case the cessation of arthritis during antisyphilitic treatment suggests, but does not prove the nature of the joint disease Arthritis may have been incidental, the previous attack having subsided entirely on rest alone It might be suggested that the patient had recurrent syphilitic synovitis [Clutton's joints], but not arthritis However, in this condition there is little if any redness, tenderness or pain—Ed)

Hypermobility and marked instability of joints are often features of "Charcot joints" Some kind of immobilization is generally required Cleveland¹⁰⁸ again presented evidence that immobilization by fusion of such joints is possible, though difficult At first, operation on a patient had produced a pseudo-arthritis in spite of prolonged postoperative immobilization, later, fusion was successfully accomplished

UNDULANT (MALTA) FEVER BANG'S DISEASE BRUCELLOSIS

The reported incidence of this disease in the United States is as follows in 1926, 46 cases, in 1927, 217, in 1928, 649, in 1929, 952, in 1930, 1420, in 1931, 1351, in 1932, 1326, in 1933, 1659, and in 1934, 1787^{109, 110} The increase is believed to be in part a true one and not just due to increased recognition of the disease Recent experiences with the disease in Tennessee, New Mexico, Iowa, New York (both city and state), Canada and Scotland were reported¹¹¹⁻¹¹⁶ The disease increasingly presents an industrial hazard to veterinarians, dairymen and meat packers, large numbers (26 to 92 per cent) of whom have it in latent form (Meyer and Geiger¹¹⁷)

Bones and joints are commonly affected (50 to 60 per cent of cases¹¹⁶), manifestations being arthralgia (migratory, often resembling rheumatic fever), myalgia, non-suppurative or suppurative arthritis, suppurative spondylitis, osteoperiostitis, or osteomyelitis The general symptoms of irregular prolonged fever, chills, anorexia, sweating, weakness, loss of weight and so on are not specific enough for diagnosis Recourse must be made to laboratory tests which, however, must be carefully interpreted as their results are variable in different stages of the disease and in different patients Criteria for diagnosis (Evans, 1934) include (1) cultivation of the organism from blood or excretions (or joints), cultures often being negative in acute, and more often negative in chronic, cases and most frequently positive in a pyrexial period, (2) positive agglutination test (usually above 1:1000, sometimes only 1:80 or 1:160), however, this may mean only that the patient has had the disease some time, it may be negative even in severe cases, tests in 5 to 16 per cent of cases being negative¹¹⁸, and (3) intradermal test with *Bacillus melitensis* antigen (vaccine), this test, however, may remain positive long after recovery, and normal people may develop cutaneous hypersensitivity thereto Specific and nonspecific cutaneous reactions can be easily differentiated, however, according to Fa-

vorite and Culp¹¹⁰ In undulant fever the blood picture resembles that of typhoid fever: leukopenia, lymphocytosis, and during fever a marked left shift of polymorphonuclear neutrophils¹¹⁰ Angle¹¹⁸ doubted the practicability of Huddleston's test of the opsonocytophagic power of the blood toward *Brucella* organisms

New cases with involvement of the locomotor system have been reported^{112, 113, 121-121} Present were migratory arthralgia or a migratory polyarthritides, a swollen left wrist with osteomyelitis from which *Brucella* organisms were isolated, and destruction of two or three contiguous vertebral bodies and intervertebral disks in various regions of the spine (Described as "spondylitis," osteomyelitis was apparently present—Ed)
